Users Guide 3.02a

February, 2002

Comments to: rootdoc@root.cern.ch

The ROOT User’s Guide:

Authors: René Brun/CERN, Fons Rademakers, Suzanne Panacek/FNAL, Damir Buskulic/Universite de Savoie/LAPP, Jörn Adamczewski/GSI, Marc Hemberger/GSI, Nick West/Oxford

Editor: Suzanne Panacek/FNAL

Special Thanks to: Philippe Canal/FNAL, Andrey Kubarovsky/FNAL
In late 1994, we decided to learn and investigate Object Oriented programming and C++ to better judge the suitability of these relatively new techniques for scientific programming. We knew that there is no better way to learn a new programming environment than to use it to write a program that can solve a real problem. After a few weeks, we had our first histogramming package in C++. A few weeks later we had a rewrite of the same package using templates. Again, a few weeks later we had another rewrite of the package without templates since we could only compile the version with templates on one single platform. Finally, after about four months we had a histogramming package that was faster and more efficient than the well-known FORTRAN based HBOOK a histogramming package. This gave us enough confidence in the new technologies to decide to continue the development. Thus was born ROOT.

Since its first public release at the end of 1995, ROOT has enjoyed an ever-increasing popularity. Currently it is being used in all major High Energy and Nuclear Physics laboratories around the world to monitor, to store and to analyze data. In the other sciences as well as the medical and financial industries, many people are using ROOT. We estimate the current user base to be around several thousand people.

In 1997, Eric Raymond analyzed in his paper "The Cathedral and the Bazaar" the development method that makes Linux such a success. The essence of that method is: "release early, release often and listen to your customers". This is precisely how ROOT is being developed. Over the last five years, many of our "customers" became co-developers. Here we would like to thank our main co-developers and contributors:

Masaharu Goto who wrote the CINT C++ interpreter. CINT has become an essential part of ROOT. Despite being 8 time zones ahead of us, we often have the feeling he is sitting in the room next door.

Valery Fine who ported ROOT to Windows and who also contributed largely to the 3-D graphics and geometry packages.

Nenad Buncic who developed the HTML documentation generation system and integrated the X3D viewer in ROOT.

Philippe Canal who developed the automatic compiler interface to CINT. In addition to a large number of contributions to many different parts of the system, Philippe is also the ROOT support coordinator at FNAL.

Suzanne Panacek who is the main author of this manual. Suzanne is also very active in preparing tutorials and giving lectures about ROOT.

Further, we would like to thank the following people for their many contributions, bug fixes, bug reports and comments:

Maarten Ballintijn, Stephen Bailey, Damir Buskulic, Federico Carminati, Mat Dobbs, Rutger v.d. Eijk, Anton Fokin, Nick van Eijndhoven, George Heintzelman, Marc Hemberger, Christian Holm Cristensen, Jacek M. Holeczek, Stephan Kluth, Marcel Kunze, Christian Lacunza, Matthew D. Langston, Michal Lijowski, Peter Malzacher, Dave Morrison, Eddy Offermann, Pasha Murali, Valeriy Onuchin, Victor Perevoztchikov, Sven Ravndal, Reiner Rohlfis, Gunther Roland, Andy Sainkov, Otto Schaale, Alexandre V. Vaniachine, Torre Wenaus and Hans Wenzel, and many more who have also contributed.

You all helped in making ROOT a great experience.

Happy ROOTing!

Rene Brun & Fons Rademakers

1 Introduction

In the mid 1990’s, René Brun and Fons Rademakers had many years of experience developing interactive tools and simulation packages. They had lead successful projects such as PAW, PIAF, and GEANT, and they knew the library they were building was the first of its kind as software libraries were reaching their limits. Although still very popular, these tools could not scale up to the challenges offered by the Large Hadron Collider, where the data is a few orders of magnitude larger than anything seen before.

At the same time, computer science had made leaps of progress especially in the area of Object Oriented Design, and René and Fons were ready to take advantage of it.

ROOT was developed in the context of the NA49 experiment at CERN. NA49 has generated an impressive amount of data and the need for new tools was inevitable. The rate provided the ideal environment to develop and test the next generation of data analysis.

One cannot mention ROOT without mentioning CINT its C++ interpreter. CINT was created by Masa Goto in Japan. It is an independent product, which ROOT is using for the command line and script processor.

ROOT was, and still is, developed in the “Bazaar style”, a term from the book “The Cathedral and the Bazaar” by Eric S. Raymond. It means a liberal, informal development style that heavily leverages the diverse and deep talent of the user community. The result is that physicists developed ROOT for themselves, this made it specific, appropriate, useful, and over time refined and very powerful.

When it comes to storing and mining large amount of data, physics plows the way with its Terabytes, but other fields and industry follow close behind as they acquire more and more data over time, and they are ready to use the true and tested technologies physics has invented. In this way, other fields and industries found ROOT useful and they have started to use it, too.

The development of ROOT is a continuous conversation between users and developers with the line between the two blurring at times and the users becoming co-developers.

In the bazaar view, software is released early and frequently to expose it to thousands of eager co-developers to pound on, report bugs, and contribute possible fixes. More users find more bugs, because more users add different ways of stressing the program. By now, after six years, many, many users have stressed ROOT in many ways, and it is quiet mature. Most likely, you will find the features you are looking for, and if you have found a hole, you are encouraged to participate in the dialog and post your suggestion or even implementation on roottalk, the ROOT mailing list.

The ROOT Mailing List

You can subscribe to roottalk, the ROOT Mailing list by registering at the ROOT web site: http://root.cern.ch/root/Registration.phtml.

You can browse the roottalk archives at:
http://root.cern.ch/root/roottalk.html

You can send your question without subscribing to: roottalk@root.cern.ch

Conventions Used in This Book

We tried to follow a style convention for the sake of clarity. Here are the few styles we used.

To show source code in scripts or source files:

```
{ 
    cout << " Hello" << endl;
    float x = 3.;
    float y = 5.5;
    int i = 101;
    cout << " x = " <<x<< " y = " <<y<< " i = " <<i<< endl;
}
```

To show the ROOT command line, we show the ROOT prompt without numbers. In the interactive system, the ROOT prompt has a line number (root [12]), for the sake of simplicity we left off the line number.

Bold monotype font indicates text for you to enter at verbatim.

Italic bold monotype font indicates a global variable, for example gDirectory.
We also used the italic bold font to highlight the comments in the code listing.

When a variable term is used, it is shown between angled brackets. In the example below the variable term <library> can be replaced with any library in the $ROOTSYS directory.

$ROOTSYS/<library>/inc

The Framework

ROOT is an object-oriented framework aimed at solving the data analysis challenges of high-energy physics. There are two key words in this definition, object oriented and framework. First, we explain what we mean by a framework and then why it is an object-oriented framework.

What is a Framework?

Programming inside a framework is a little like living in a city. Plumbing, electricity, telephone, and transportation are services provided by the city. In your house, you have interfaces to the services such as light switches, electrical outlets, and telephones. The details, for example the routing algorithm of the phone switching system, are transparent to you as the user. You do not care, you are only interested in using the phone to communicate with your collaborators to solve your domain specific problems.

Programming outside of a framework may be compared to living in the country. In order to have transport and water, you will have to build a road and dig a well. To have services like telephone and electricity, you will need to route the wires to your home. In addition, you cannot build some things you need. For example, you cannot build a commercial airport or your own laboratory. From a global perspective, it would make no sense for everyone to build their own airport. You see, you will be very busy building the infrastructure (or framework) before you can use the phone to communicate with your collaborators and have a drink of water at the same time.

In software engineering, it is much the same way. A framework is the basic utilities and services, such as I/O and graphics, are provided. In addition, ROOT, being a HEP analysis framework, it provides a large selection of HEP specific utilities such as histograms, fits, etc. The framework is that you are constrained to, as you are constrained to using the routing algorithm provided by your telephone service. You also have to learn the framework interfaces, which is an analogy of learning how to use the telephone.

If you are interested in doing physics, a good HEP framework will save you much work.

Below is a list of the more commonly used components of ROOT:

- Command Line Interpreter
- Histograms and Fitting
- Graphic User Interface widgets
- 2D Graphics
- I/O
- Collection Classes
- Script Processor

There are also less commonly used components, these are:

- 3D Graphics

Advantages of Frameworks

The benefits of frameworks can be summarized as follows:

- Less code to write: The programmers should be able to use and reuse the majority of the code. Basic functionality, such as fitting and histogramming are implemented and ready to use and customize.
- More reliable and robust code: Code inherited from a framework has already been tested and integrated with the rest of the framework.
- More consistent and modular code: Code reuse provides consistency and common capabilities between programs. In addition, frameworks also make it easier to build programs in multiple languages.
- More focus on areas of expertise: Users can concentrate on their particular problem domain. They don’t have to be experts at writing user interfaces, graphics, or networking to use the frameworks that provide those services.

Why Object-Oriented?

Object-Oriented Programming offers considerable benefits compared to Procedure-Oriented Programming:

- Encapsulation enforces data abstraction and increases opportunity for reuse.
- Sub-classing and inheritance make it possible to extend and modify objects.
- Class hierarchies and containment hierarchies provide a flexible mechanism for modeling real-world objects and the relationships among them.
- Complexity is reduced because there is little growth of the global state. The state is contained within each object, rather than scattered through the program in the form of global variables.
- Often, it is the interfaces that limit the applicability of the program, yet remains relatively static. Increases opportunity for reuse of design.

Installing ROOT

The installation and building of ROOT is described in Appendix A: Install and Build ROOT. You can download the binaries (7 MB to 11 MB depending on the platform), or the source (about 3.4 MB). ROOT can be compiled by the GNU g++ compiler on most Unix platforms.

ROOT is currently running on the following platforms:

- Intel x86 Linux (g++, egcs and KAI/KCC)
- Intel Itanium Linux (g++)
- HP HP-UX 10.x (HP CC and aCC, egcs1.2 C++ compilers)
- IBM AIX 4.1 (xlc compiler and egcs1.2)
- Sun Solaris for SPARC (SUN C++ compiler and egcs)
- Sun Solaris for x86 (SUN C++ compiler)
- Sun Solaris for x86 KAI/KCC
- Compaq Alpha OSF1 (egcs1.2 and DEC/CXX)
The Organization of the ROOT Framework

Now we know in abstract terms what the ROOT framework is, let's look at the physical directories and files that come with the installation of ROOT.

You may work on a platform where your system administrator has already installed ROOT. You will need to follow the specific development environment for your setup and you may not have write access to the directories. In any case, you will need an environment variable called $ROOTSYS, which holds the path of the top directory.

> echo $ROOTSYS
/home/root

In the $ROOTSYS directory are examples, executables, tutorials, header files, and if you opted to download the source it is also here. The directories of special interest to us are bin, tutorials, lib, test, and include. The diagram on the next page shows the contents of these directories.
$ROOTSYS/bin

The bin directory contains several executables:

- root is the interactive interface to ROOT.
- rootd is the daemon for remote ROOT file access (see proofd). The core library (libCore.so) is the actual PROOF process, which is started by rootd after a user, has successfully been authenticated.
- proofd is the daemon for remote ROOT file access (see proofd). The core library (libCore.so) is the actual PROOF process, which is started by rootd after a user, has successfully been authenticated.
- root.exe is the executable that shows the ROOT splash screen and calls root
- rootcint is the C++ interpreter version of root.exe that requires the C++ interpreter and not ROOT. That is the reason these two are separate. A program referencing only C++ classes and not ROOT only needs libCint.so and libCore.so, which can be used independently of libCore.so. It is used by some of CINT's install scripts to generate dictionary. It is used by some of CINT's install scripts to generate dictionary.
- root-config is a script returning the needed compile flags and is the pure CINT version of root.exe. It is used by some of CINT's install scripts to generate dictionary. It is used by some of CINT's install scripts to generate dictionary.
- makedepend is a modified version of makedepend that works for C++. It is used by some of CINT's install scripts to generate dictionary. It is used by some of CINT's install scripts to generate dictionary.
- rmkdepend is a script that works for C++. It is used by some of CINT's install scripts to generate dictionary. It is used by some of CINT's install scripts to generate dictionary.

$ROOTSYS/lib

There are several ways to use ROOT. One way is to run the executable by typing root at the system prompt. Another way is to link with the ROOT libraries and make the ROOT classes available in your own program.

Here is a short description for each library, the ones marked with a * are only needed in all ROOT applications, but libCore can be used independently of libCore.so. The core library (libCore.so) is the actual PROOF process, which is started by root after a user, has successfully been authenticated. If you use a debugger such as gdb, you will need to compile and link with ROOT.

- libCore.so is the Base classes.
- libEG.so is the abstract event generator interface classes.
- libEGPythia.so is the Pythia5 event generator interface.
- libEGPythia6.so is the Pythia6 event generator interface.
- libEGVenus.so is the Venus event generator interface.
- libGraf3d.so is the 3D graphics primitives.
- libGpad.so is the 2D graphics primitives.
- libGX11TTF.so is the TrueType fonts providing TrueType fonts.
- libHistPainter.so is the histogram painting classes.
- libHist.so is the histogram classes.
- libHistHtml.so is the HTML documentation generation system.
- libMatrix.so is the matrix and vector manipulation.
- libMinuit.so is the MINUIT fitter.
- libNew.so is the special global new/delete, provides extra memory checking and interface for shared memory (optional).
- libPhysics.so is the physics quantity manipulation classes (TLorentzVector, etc.)
- libPostScript.so is the PostScript interface

Library Dependencies

The libraries are designed and organized to minimize dependencies, such that you can include just enough code for the task at hand rather than having to include all libraries or one monolithic chunk.

The core library (libCore.so) contains the essentials; it needs to be included in all ROOT applications. In the diagram, source that libCore.so is made up of Base classes. Container classes. Meta information classes. Networking classes. Operating system specific classes and the ZIP algorithm used for compression of the ROOT files.

The CINT library (libCint.so) is also needed in all ROOT applications, but libCint.so can be used independently of libCore.so. In case you only need the C++ interpreter and no ROOT. That is the reason these two are separate.

A program referencing only TOOLS can opt out these two and link with libCint.so and libCore.so. The libraries are designed and organized to minimize dependencies, such that you can include just enough code for the task at hand rather than having to include all libraries or one monolithic chunk.

- libProof.so is the parallel ROOT Facility classes.
- libRFIO.so is the interface to CERN RFIO remote I/O system.
- libThread.so is the Thread classes.
- libThreadLayer.so is the Thread layer classes.
- libThreadDrawer.so is the Thread drawing classes.
- libThreadDrawer.so is the graphical Tree query interface.
- libThreadDrawer.so is the X3D system used for fast 3D display.
A batch program, one that does not have a graphic display, which creates, fills, and saves histograms and trees, only needs the core (libCore and libCint), libHist and libTree. If other libraries are needed, ROOT loads them dynamically. For example if the TreeViewer is used, libTreePlayer and all the libraries that the TreePlayer box below has an arrow to will be loaded. The difference between libHist and libHistPainter is that the former needs to be explicitly linked and the latter will be loaded automatically at runtime when needed. If the diagram, the dark boxes outside of the core are automatic. Of course, if one wants to access an automatic library directly, it has to be explicitly linked also.

An example of a dynamically linked library is Minuit. To create and fill histograms you need to link libHist. If the code has a call to fit the histogram, the “Fitter” will check if Minuit is already loaded and if not it will dynamically load it.

$ROOTSYS/test

The test directory contains many example scripts. They assume some basic knowledge of ROOT and for the new user we recommend reading the chapters: Histograms and Input/Output before first using the examples. The more experienced user can jump to chapter 7. The tutorials and tests to find more explicit and specific information about how to build and run the examples.

$ROOTSYS/include

The include directory contains all the header files, this is especially important because the header files contain the class definitions.

$ROOTSYS/<library>

The directories we explored above are available when downloading the binaries or the source. When downloading the source you also get a directory for each library with the corresponding header and source files. Each library directory contains an inc and src subdirectory. These directories contain the list of class definitions. For example, the physics library contains these class definitions:

```
> ls -m $ROOTSYS/physics/inc
CVS, LinkDef.h, TLorentzRotation.h, TLorentzVector.h,
TRotation.h, TVector2.h, TVector3.h
```

The $ROOTSYS/test directory is a gold mine of ROOT-wisdom nuggets, and we encourage you to explore and exploit it. However, we recommend that the new user read the chapters. The chapter Tutorials and Tests, has instructions on how to build all the programs and goes over the examples.

```
$ROOTSYS/physics/inc
CVS, LinkDef.h, TLorentzRotation.h, TLorentzVector.h,
TRotation.h, TVector2.h, TVector3.h
```

We see these source files:

- hworld.cxx - Small program showing basic graphics.
- guitest.cxx - Example usage of the ROOT GUI classes
- Hello.cxx - Dancing text example
- Aclock.cxx - Analog clock (a la X11 xclock)
- Tetris.cxx - The famous Tetris game (using ROOT basic graphics)
- stress.cxx - Important ROOT stress testing program.

The $ROOTSYS/test directory is a gold mine of ROOT-wisdom nuggets, and we encourage you to explore and exploit it. However, we recommend that the new user read the chapters. The chapter Tutorials and Tests, has instructions on how to build all the programs and goes over the examples.
How to Find More Information

The ROOT web site has up-to-date documentation. The ROOT source code automatically generates this documentation, as each class is explicitly documented on its own web page, which is always up to date with the latest official release of ROOT. The class index web pages can be found at http://root.cern.ch/root/html/ClassIndex.html. Each page contains a class description, and an explanation of each method. It shows the class it was derived from, and if you jump to the parent class page by clicking on the class name. If you want more detail, you can even see the source. In addition to this, the site contains tutorials, "How To's", and a list of publications and example applications.
We begin by showing you how to use ROOT interactively. There are two examples to click through and learn how to use the GUI. We continue by using the command line, and explaining the coding conventions, global variables and the environment setup.

If you have not installed ROOT, you can do so by following the instructions in the appendix, or on the ROOT web site:

http://root.cern.ch/root/Availability.html

## Start and Quit a ROOT Session

To start ROOT you can type `root` at the system prompt. This starts up CINT the ROOT command line C/C++ interpreter, and it gives you the ROOT prompt (`root [0]`).

```
root [0]
```

It is possible to launch ROOT with some command line options, as shown below:

```
% root -l
Usage: root [-l] [-b] [-n] [-q] [file1.C ... fileN.C]
Options:
  -l : do not show the image logo (splash screen)
  -b : run in batch mode without graphics
  -n : do not execute logon and logoff macros as specified in .rootrc
  -q : exit after processing command line script files
```

- `-b`: Run in batch mode, without graphics display. This mode is useful in case one does not want to set the DISPLAY or cannot do it for some reason.
- `-n`: Usually, launching a ROOT session will execute a logon script and quitting will execute a logoff script. This option prevents the execution of these two scripts.
- `–q`: Exit after processing command line script files. Retrieving previous commands and navigating on the Command Line.

For example if you would like to run a script in the background, exit after execution, and redirect the output into a file, use the following syntax:

```
root -b -q myMacro.C > myMacro.log
```

For a quicker execution (i.e. compiled speed rather than interpreted speed), you can build a shared library with ACLiC (see the Chapter on CINT) and then use the shared library on the command line.

```
root -b -q myMacro.so > myMacro.log
```

ROOT’s powerful C/C++ interpreter gives you access to all available ROOT classes, global variables, and functions via a command line. By typing C++ statements at the prompt, you can create objects, call functions, execute scripts, etc. For example:

```
root[] l=sgt(9)
(double)4.000000000000000e+00
root[] for (int i = 0; i<5; i++) cout << "Hello" << i << endl
  Hello 0
  Hello 1
  Hello 2
  Hello 3
  Hello 4
root[] .q
```
Exit ROOT
To quit the command line type .q.

First Example: Using the GUI
In this example, we show how to use a function object, and change its
attributes using the GUI. Again, start ROOT.

Note: The GUI on MS-Windows looks and works a little different from the one
on UNIX. We are working on porting the new GUI class to Windows. Once
they are available, the GUI will be changed to be identical to the one in UNIX.
In this book, we used the UNIX GUI.

```c
% root
...
root[] TF1 f1("func1", "sin(x)/x", 0, 10)
root[] f1.Draw()
```

You should see something like this:

![Graph of sin(x)/x function](image)

Drawing a function is interesting, but it is not unique to a function. Evaluating
and calculating the derivative and integral are what one would expect from a
function. TF1, the function class defines these methods for us.

```c
root[] f1.Eval(3)
(Double_t)4.70400026866224020e-02
root[] f1.Derivative(3)
(Double_t)(-3.45675056671992330e-01)
root[] f1.Integral(0,3)
(Double_t)1.84865252799946810e+00
root[] f1.Draw()
```

Note that by default TF1::Paint, the method that draws the function,
computes 100 equidistant points to draw it. You can set the number of points
to a higher value with the TF1::SetNpx() method:

```c
root[] f1s.SetNpx(2000);
```

Classes, Methods and Constructors
Object oriented programming introduces objects, which have data members
and methods.

The line `TF1 f1("func1", "sin(x)/x", 0, 10)` creates an object
named `f1` of the class `TF1` that is a one-dimensional function. The type of an
object is called a class. The object is called an instance of a class. When
a method builds an object, it is called a constructor.

```c
TF1 f1("func1", "sin(x)/x", 0, 10)
```

In our constructor, we used `sin(x)/x`, which is the function to use, and 0
and 10 are the limits. The first parameter, `func1` is the name of the object
f1. Most objects in ROOT have a name. ROOT maintains a list of objects
that can be searched to find any object by its given name (in our example
func1).

The syntax to call an object's method, or if one prefers, to make an object do
something is:

```c
object.method_name(parameters)
```

This is the usual way of calling methods in C++. The dot can be replaced by
"->" if object is a pointer. In compiled code, the dot MUST be replaced by
a "->" if object is a pointer.

```c
object_ptr->method_name(parameters)
```

So now, we understand the two lines of code that allowed us to draw our
function. `f1.Draw()` stands for "call the method `Draw` associated with
the object `f1` of class `TF1`". We will see the advantages of using objects and
classes very soon.

One point, the ROOT framework is an object oriented framework; however
this does not prevent the user from calling plain functions. For example, most
simple scripts have functions callable by the user.

User interaction
If you have quit the framework, try to draw the function `sin(x)/x` again.
Now, we can look at some interactive capabilities. Every object in a window
(which is called a Canvas) is in fact a graphical object in the sense that you
can grab it, resize it, and change some characteristics with a mouse click.

For example, bring the cursor over the x-axis. The cursor changes to a hand
with a pointing finger when it is over the axis. Now, left click and drag the
mouse along the axis to the right. You have a very simple zoom.

When you move the mouse over any object, you can get access to selected
methods by pressing the right mouse button and obtaining a context menu. If
you try this on the function `(TF1)`, you will get a menu showing available
methods. The other objects on this canvas are the title a `TPaveText`, the x
and y-axis, which are `TAxis` objects, the frame a `TFrame`, and the canvas a
TCanvas. Try clicking on these and observe the context menu with their methods.

For the function, try for example to select the `SetRange` method and put -10, 10 in the dialog box fields. This is equivalent to executing the member function `f1.SetRange(-10,10)` from the command line prompt, followed by `f1.Draw()`.

Here are some other options you can try. For example, select the `DrawPanel` item of the popup menu.

You will see a panel like this:

Try to resize the bottom slider and click Draw. You can zoom your graph. If you click on "lego2" and "Draw", you will see a 2D representation of your graph:

This 2D plot can be rotated interactively. Of course, ROOT is not limited to 1D graphs - it is possible to plot real 2D functions or graphs. There are numerous ways to change the graphical options/colors/fonts with the various methods available in the popup menu.

Once the picture suits your wishes, you may want to see the code you should put in a script to obtain the same result. To do that, choose the "Save as canvas.C" option in the "File" menu. This will generate a script showing the various options. Notice that you can also save the picture in PostScript or GIF format.

One other interesting possibility is to save your canvas in native ROOT format. This will enable you to open it again and to change whatever you like, since all the objects associated to the canvas (histograms, graphs) are saved at the same time.
Second Example: Building a Multi-pad Canvas

Let's now try to build a canvas (i.e. a window) with several pads. The pads are sub-windows that can contain other pads or graphical objects.

```
root[] TCanvas *MyC = new TCanvas("MyC","Test canvas",1)
```

Once again, we called the constructor of a class, this time the class TCanvas. The difference with the previous constructor call is that we want to build an object with a pointer to it.

Next, we call the method Divide of the TCanvas class (that is TCanvas::Divide()), which divides the canvas into four zones and sets up a pad in each of them.

```
root[] MyC->Divide(2,2)
```

```
root[] MyC->cd(1)
```

```
f1->Draw()
```

Now, the function f1 will be drawn in the first pad. All objects will now be drawn in that pad. To change the active pad, there are three ways:

- Click on the middle button of the mouse on an object, for example a pad. This sets this pad as the active one
- Use the method TCanvas::cd with the pad number, as was done in the example above:

```
root[] MyC_3->cd()    
```

The third pad will be selected since you called TPad::cd() for the object MyC_3. ROOT automatically found the pad that was named MyC_3 when you typed it on the command line (see ROOT/CINT Extensions to C++).

The obvious question is: what is the relation between a canvas and a pad? In fact, a canvas is a pad that spans through an entire window. This is nothing else than the notion of inheritance. The TPad class is the parent of the TCanvas class.

Printing the Canvas

To print a canvas click on the File menu and select Print. This will create a postscript file containing the canvas. The file is named <canvasname>.ps. Then you can send the postscript file to your printer.

---

The ROOT Command Line

We have briefly touched on how to use the command line, and you probably saw that there are different types of commands.

1. CINT commands start with "."

```
root[] .?
//this command will list all the CINT commands
```

```
root[] .l <filename>
```

```
root[] .x <filename>
```

2. SHELL commands start with "!" for example:

```
root[] .! ls
```

3. C++ commands follow C++ syntax (almost)

```
root[] TBrowser *b = new TBrowser()
```

CINT Extensions

We can see that some things are not standard C++. The CINT interpreter has several extensions. See the section ROOT/CINT Extensions to C++ in chapter CINT the C++ Interpreter

Helpful Hints for Command Line Typing

The interpreter knows all the classes, functions, variables, and user defined types. This enables ROOT to help the user complete the command line. For example we do not know yet anything about the TLine class. We can use the Tab feature to get help. Where <TAB> means type the <TAB> key. This lists all the classes starting with TL.

```
root[] l = new TL<TAB>
```

TLeaf
TLeafB
TLeafC
TLeafD
TLeafF
TLeafI
TLeafObject
TLeafS
TLine
TLatex
TLegendEntry
TLegend
TLink
TList
TListIter
TLazyMatrix
TLazyMatrixD

This lists the different constructors and parameters for TLine.
Multi-line Commands

You can use the command line to execute multi-line commands. To begin a multi-line command you must type a single left curly bracket {, and to end it you must type a single right curly bracket }.

For example:

```
root [] {
end with '}' Int_t j = 0;
end with '}' for (Int_t i = 0; i < 3; i++)
end with '}' j = j + i;
end with '}' cout << "i = " << i << " j = " << j << endl;
end with '}'
i = 0, j = 0
i = 1, j = 1
i = 2, j = 3
```

It is more convenient to edit scripts than the command line, and if your multi-line commands are getting unmanageable you may want to start a script instead.

Conventions

In this paragraph, we will explain some of the conventions used in ROOT source and examples.

Coding Conventions

From the first days of ROOT development, it was decided to use a set of coding conventions. This allows a consistency throughout the source code. Learning these will help you identify what type of information you are dealing with and enable you to understand the code better and quicker. Of course, you can use whatever convention you want but if you are going to submit some code for inclusion into the ROOT sources you will need to use these. These are the coding conventions:

- Classes begin with T: TTree, TBranch
- Non-class types end with _t: Int_t
- Data members begin with f: fChain
- Member functions begin with a capital: Loop()
- Constants begin with k: kInitialSize, kRed
- Global variables begin with g: gEnv
- Static data members begin with fg: fgTokenClient
- Enumeration types begin with E: EColorLevel
- Locals and parameters begin with a lower case: nbytes
- Getters and setters begin with Get and Set: SetLast(), GetFirst()
- Machine Independent Types

Different machines may have different lengths for the same type. The most famous example is the int type. It may be 16 bits on some old machines and 32 bits on some newer ones.

To ensure the size of your variables, use these predefined types in ROOT:

- Char_t: Signed Character 1 byte
- Uchar_t: Unsigned Character 1 byte
- Short_t: Signed Short integer 2 bytes
- UShort_t: Unsigned Short integer 2 bytes
- Int_t: Signed integer 4 bytes
- UInt_t: Unsigned integer 4 bytes
- Long_t: Signed long integer 8 bytes
- ULong_t: Unsigned long integer 8 bytes
- Float_t: Float 4 bytes
- Double_t: Float 8 bytes
- Bool_t: Boolean (0=false, 1=true)

If you do not want to save a variable on disk, you can use int or Int_t, the result will be the same and the interpreter or the compiler will treat them in exactly the same way.

 TObject

In ROOT, almost all classes inherit from a common base class called TObject. This kind of architecture is also used in the Java language. The TObject class provides default behavior and protocol for all objects in the ROOT system. The main advantage of this approach is that it enforces the common behavior of the derived classes and consequently it ensures the consistency of the whole system.

TObject provides protocol, i.e. (abstract) member functions, for:

- Object I/O (Read(), Write())
- Error handling (Warning(), Error(), SysError(), Fatal())
- Sorting (IsSortable(), Compare(), IsEqual(), Hash())
- Inspection (Dump(), Inspect())
- Printing (Print())
- Drawing (Draw(), Paint(), ExecuteEvent())
- Bit handling (SetBit(), TestBit())
- Memory allocation (operator new and delete, IsOnHeap())
- Access to meta information (IsA(), InheritsFrom())
- Object browsing (Browse(), IsFolder())

See "The Role of TObject" in the chapter "Adding a Class."
Global Variables

ROOT has a set of global variables that apply to the session. For example, gDirectory always holds the current directory, and gStyle holds the current style. All global variables begin with "g" followed by a capital letter.

gROOT
The single instance of TROOT is accessible via the global gROOT and holds information relative to the current session. By using the gROOT pointer you get the access to basically every object created in a ROOT program. The TROOT object has several lists pointing to the main ROOT objects.

The Collections of gROOT
During a ROOT session, the gROOT keeps a series of collections to manage objects. These can be accessed with the gROOT::GetListO methods.

```cpp
gROOT->GetListOfClasses()
gROOT->GetListOfColors()
gROOT->GetListOfTypes()
gROOT->GetListOfGlobals()
gROOT->GetListOfMappedFiles()
gROOT->GetListOfFunctions()
gROOT->GetListOfCanvases()
gROOT->GetListOfTypes()
gROOT->GetListOfSpecials()
gROOT->GetListOfBrowsers()
gROOT->GetListOfMessageHandlers()
```

These methods return a TSeqCollection, meaning a collection of objects, and they can be used to do list operations such as finding an object, or traversing the list and calling a method for each of the members. See the TCollection class description for the full set of methods supported for a collection.

For example, to find a canvas called c1:

```cpp
root[] gROOT->GetListOCanvases()]->FindObject("c1")
```

This returns a pointer to a TObject, and before you can use it as a canvas you will need cast it to a TCanvas*.

gFile

gFile is the pointer to the current opened file.

gDirectory

gDirectory is a pointer to the current directory. The concept and role of a directory is explained in chapter Input/Output.

gPad
A graphic object is always drawn on the active pad. It is convenient to access the active pad, no matter what it is. For that we have gPad that is always pointing to the active pad. For example, if you want to change the fill color of the active pad to blue, but you do not know its name, you can use gPad.

```cpp
root[] gPad->SetFillColor(38)
```

To get the list of colors, if you have an open canvas, click in the "View" menu, selecting the "Colors" entry.

gRandom

gRandom is a pointer to the current random number generator. By default, it points to a TRandom object. Setting the seed to 0 implies that the seed will be generated from the time. Any other value will be used as a constant.

The following basic random distributions are provided:

- `Gaus(mean, sigma)`
- `Rndm()`
- `Landau(mean, sigma)`
- `Poisson(mean)`
- `Binomial(ntot, prob)`

You can customize your ROOT session by replacing the random number generator. You can delete gRandom and recreate it with your own:

```cpp
root[] delete gRandom;
root[] gRandom = new TRandom3(0);  //seed=0
```

TRandom3 derives from TRandom and is a very fast generator with higher periodicity.

gEnv

gEnv is the global variable (of type TEnv) with all the environment settings for the current session. This variable is set by reading the contents of a .rootrc file (or $ROOTSYS/etc/system.rootrc) at the beginning of the session. See Environment Setup below for more information.

History File

You can use the up and down arrow at the command line, to access the previous and next command. The commands are recorded in the history file $HOME/.root_hist. It contains the last 100 commands. It is a text file, and you can edit and cut and paste from it.

You can specify the history file in the system.rootrc file (see below), by setting the Rint.History option. You can also turn off the command logging in the system.rootrc file with the option: Rint.History: -
Environment Setup

The behavior of a ROOT session can be tailored with the options in the rootrc file. At start-up, ROOT looks for a rootrc file in the following order:

- ./rootrc //local directory
- $HOME/.rootrc //user directory
- $ROOTSYS/etc/system.rootrc //global ROOT directory

If more than one rootrc file is found in the search paths above, the options are merged, with precedence local, user, global.

While in a session, to see current settings, you can do

```c
root[] gEnv->Print()
```

The rootrc file typically looks like:

```plaintext
# Path used by dynamic loader to find shared libraries
Unix.*.Root.DynamicPath:  .:~/.rootlibs:$ROOTSYS/lib
Unix.*.Root.MacroPath:   .:/rootmacros:$ROOTSYS/macros

# Path where to look for TrueType fonts
Unix.*.Root.UseTTFonts:     true
Unix.*.Root.TTFontPath:     ...

# Activate memory statistics
Rint.Root.MemStat:       1
Rint.Load:               rootalias.C
Rint.Logon:              rootlogon.C
Rint.Logoff:             rootlogoff.C
Rint.Canvas.MoveOpaque:  false
Rint.Canvas.HighLightColor:  5
```

The various options are explained in $ROOTSYS/etc/system.rootrc.

The .rootrc file contents are combined. For example, if the flag to use true type fonts is set to true in one of the system.rootrc files, you have to explicitly overwrite it and set it to false. Removing the UseTTFonts statement in the local .rootrc file will not disable true fonts.

The Script Path

ROOT looks for scripts in the path specified in the rootrc file in the Root.Macro.Path variable. You can expand this path to hold your own directories.

Logon and Logoff Scripts

The rootlogon.C and rootlogoff.C files are script loaded and executed at start-up and shutdown. The rootalias.C file is loaded but not executed. It typically contains small utility functions. For example, the rootalias.C script that comes with the ROOT distributions and is in the $ROOTSYS/tutorials defines the function edit(char *file). This allows the user to call the editor from the command line. This particular

```c
root [] edit( "cl.C" )
```

function will start the VI editor if the environment variable EDITOR is not set.

For more details, see $ROOTSYS/tutorials/rootalias.C.

Tracking Memory Leaks

You can track memory usage and detect leaks by monitoring the number of objects that are created and deleted (see TObjectTable). To use this facility, edit the file .rootrc if you have this file or $ROOTSYS/etc/system.rootrc and edit or add the two following lines:

```c
Root.MemStat:            1
Root.ObjectStat:         1
```

In your code, or on the command line you can type the line:

```c
gObjectTable->Print();
```

This line will print the list of active classes and the number of instances for each class. By comparing consecutive print outs, you can see objects that you forgot to delete.

Note that this method cannot show leaks coming from the allocation of non-objects or classes unknown to ROOT.

Memory Checker

A memory checking system was developed by D.Bertini and M.Ivanov and added in ROOT version 3.02.07.

To activate the memory checker you can set the resource Root.MemCheck to 1 (e.g.:

```c
Root.MemCheck: 1
```

) in the .rootrc file. You also have to link with libNew.so (e.g. use root-config --new --libs) or use rootn.exe. When these settings are in place, you will find a file "memcheck.out" in the directory where you started your ROOT program after the completion of the program execution.

You can also set the resource Root.MemCheckFile to the name of a file. The memory information will be written to that file. The contents of this memcheck.out can be analyzed and transformed into printable text via the memprobe program (in $ROOTSYS/bin).

Converting HBOOK/PAW files

ROOT has a utility called h2root that you can use to convert your HBOOK/PAW histograms or ntuples files into ROOT files. To use this program, you type the shell script command:

```c
h2root <hbookfile> <rootfile>
```

If you do not specify the second parameter, a file name is automatically generated for you. If hbookfile is of the form file.hbook, then the ROOT file will be called file.root.
This utility converts HBOOK histograms into ROOT histograms of the class TH1F. HBOOK profile histograms are converted into ROOT profile histograms (see class TProfile). HBOOK row-wise and column-wise ntuples are automatically converted to ROOT Trees (see the chapter on Trees). Some HBOOK column-wise ntuples may not be fully converted if the columns are an array of fixed dimension (e.g. var[6]) or if they are a multi-dimensional array.

HBOOK integer identifiers are converted into ROOT named objects by prefixing the integer identifier with the letter “h” if the identifier is a positive integer and by “h_” if it is a negative integer identifier.

In case of row-wise or column-wise ntuples, each column is converted to a branch of a tree.

Note that h2root is able to convert HBOOK files containing several levels of sub-directories.

Once you have converted your file, you can look at it and draw histograms or process ntuples using the ROOT command line. An example of session is shown below:

```c
// this connects the file hbookconverted.root
root[] TFile f("hbookconverted.root");

// display histogram named h10 (was HBOOK id 10)
root[] h10.Draw();

// display column "var" from ntuple h30
root[] h30.Draw("var");
```

You can also use the ROOT browser (see TBrowser) to inspect this file.

The chapter on trees explains how to read a Tree. ROOT includes a function TTree::MakeClass to automatically generate the code for a skeleton analysis function (see the chapter Example Analysis).

In case one of the ntuple columns has a variable length (e.g. px[ntrack]), h.Draw("px") will histogram the px column for all tracks in the same histogram. Use the script quoted above to generate the skeleton function and create/fill the relevant histogram yourself.
3 Histograms

This chapter covers the functionality of the histogram classes. We begin with an overview of the histogram classes and their inheritance relationship. Then we give instructions on the histogram features.

We have put this chapter ahead of the graphics chapter so that you can begin working with histograms as soon as possible. Some of the examples have graphics commands that may look unfamiliar to you. These are covered in the chapter on Input/Output.

The Histogram Classes

ROOT supports the following histogram types:

1-D histograms:
- TH1C: are histograms with one byte per channel. Maximum bin content = 255
- TH1S: are histograms with one short per channel. Maximum bin content = 65,535
- TH1F: are histograms with one float per channel. Maximum precision 7 digits
- TH1D: are histograms with one double per channel. Maximum precision 14 digits

2-D histograms:
- TH2C: are histograms with one byte per channel. Maximum bin content = 255
- TH2S: are histograms with one short per channel. Maximum bin content = 65535
- TH2F: are histograms with one float per channel. Maximum precision 7 digits
- TH2D: are histograms with one double per channel. Maximum precision 14 digits

3-D histograms:
- TH3C: are histograms with one byte per channel. Maximum bin content = 255
- TH3S: are histograms with one short per channel. Maximum bin content = 65535
- TH3F: are histograms with one float per channel. Maximum precision 7 digits
- TH3D: are histograms with one double per channel. Maximum precision 14 digits

Profile histograms:
- TProfile: one dimensional profiles
- TProfile2D: two dimensional profiles

Profile histograms are used to display the mean value of Y and its RMS for each bin in X. Profile histograms are in many cases an elegant replacement of two-dimensional histograms. The inter-relation of two measured quantities X and Y can always be visualized with a two-dimensional histogram or scatter-plot. If Y is an unknown but single-valued approximate function of X, it will have greater precisions in a profile histogram than in a scatter plot.

All histogram classes are derived from the base class TH1. This image shows the class hierarchy of the histogram classes.

Creating Histograms

Histograms are created with constructors:

```c
TH1F *h1 = new TH1F("h1","h1 title",100,0,4.4);
TH2F *h2 = new TH2F("h2","h2 title",40,0,4,30,-3,3);
```

The parameters to the TH1 constructor are: the name of the histogram, the title, the number of bins, the x minimum, and x maximum.

Histograms may also be created by:
- Calling the Clone method of an existing histogram (see below)
- Making a projection from a 2-D or 3-D histogram (see below)
- Reading a histogram from a file

When a histogram is created, a reference to it is automatically added to the list of in-memory objects for the current file or directory. This default behavior...
can be disabled for an individual histogram or for all histograms by setting a global switch.

Here is the syntax to set the directory of a histogram:

```cpp
// to set the in-memory directory for h the current histogram
h->SetDirectory(0);
// global switch to disable
TH1::AddDirectory(kFALSE);
```

When the histogram is deleted, the reference to it is removed from the list of objects in memory. In addition, when a file is closed, all histograms in memory associated with this file are automatically deleted. See chapter Input/Output.

### Fixed or Variable Bin Size

All histogram types support fixed or variable bin sizes. 2-D histograms may have fixed size bins along X and variable size bins along Y or vice-versa. The functions to fill, manipulate, draw, or access histograms are identical in both cases.

To create a histogram with variable bin size one can use this constructor:

```cpp
TH1(const char name,const char* title,Int_t nbins,Float_t *xbins)
```

The parameters to this constructor are:
- `title`: histogram title
- `nbins`: number of bins
- `xbins`: array of low-edges for each bin. This is an array of size `nbins+1`

Each histogram always contains three TAxis objects: `fXaxis`, `fYaxis`, and `fZaxis`. To access the axis parameters first get the axis from the histogram, and then call the TAxis access methods.

```cpp
TAxis *xaxis = h->GetXaxis();
Double_t binCenter = xaxis->GetBinCenter(bin);
```

See class TAxis for a description of all the access methods. The axis range is always stored internally in double precision.

### Bin numbering convention

For all histogram types: `nbins, xlow, xup`

Bin# 0 contains the underflow.
Bin# 1 contains the first bin with low-edge (xlow INCLUDED).
The second to last bin (bin# `nbins`) contains the upper-edge (xup EXCLUDED).
The Last bin (bin# `nbins+1`) contains the overflow.

In case of 2-D or 3-D histograms, a "global bin" number is defined. For example, assuming a 3-D histogram with `binx, biny, binz`, the function returns a global/linear bin number.

```cpp
Int_t bin = h->GetBin(binx,biny,binz);
```

This global bin is useful to access the bin information independently of the dimension.

### Re-binning

At any time, a histogram can be re-binned via the `TH1::Rebin` method. It returns a new histogram with the re-binned contents. If bin errors were stored, they are recomputed during the re-binning.

### Filling Histograms

A histogram is typically filled with statements like:

```cpp
h1->Fill(x);
```

```cpp
h1->Fill(x,w);
```

```cpp
// with weight
h2->Fill(x,y);
```

```cpp
h2->Fill(x,y,w);
```

```cpp
h3->Fill(x,y,z);
```

```cpp
h3->Fill(x,y,z,w);
```

The `Fill` method computes the bin number corresponding to the given `x`, `y` or `z` argument and increments this bin by the given weight. The `Fill` method returns the bin number for 1-D histograms or global bin number for 2-D and 3-D histograms. If `TH1::Sumw2` has been called before filling, the sum of squares is also stored.

One can also increment a bin number directly by calling

```cpp
TH1::AddBinContent(). Replace the existing content via
```

```cpp
TH1::SetBinContent, and access the bin content of a given bin via
```

```cpp
TH1::GetBinContent.
```

### Automatic Re-binning Option

By default, the number of bins is computed using the range of the axis. You can change this to automatically re-bin by setting the automatic re-binning option:

```cpp
h->SetBit(TH1::kCanRebin);
```

Once this is set, the `Fill` method will automatically extend the axis range to accommodate the new value specified in the `Fill` argument. The method used is to double the bin size until the new value fits in the range, merging bins two by two.

This automatic binning options is extensively used by the `TTree::Draw` function when drawing histograms of variables in TTrees with an unknown range. The automatic binning option is supported for 1-D, 2-D and 3-D histograms.

During filling, some statistics parameters are incremented to compute the mean value and root mean square with the maximum precision. In case of histograms of type `TH1C, TH1S, TH2C, TH2S, TH3C, TH3S` a check is made that the bin contents do not exceed the maximum positive capacity.
Histograms of all types may have positive or/and negative bin contents.

Random Numbers and Histograms

TH1::FillRandom can be used to randomly fill a histogram using the contents of an existing TF1 function or another TH1 histogram (for all dimensions). For example, the following two statements create and fill a histogram 10000 times with a default Gaussian distribution of mean 0 and sigma 1:

```c
TH1F h1("h1","histo from a gaussian",100,-3,3);
h1.FillRandom("gaus",10000);
```

To fill a histogram following the distribution in an existing histogram you can use the second signature of TH1::FillRandom.

This code snippet assumes that h is an existing histogram (TH1).

```c
root [] TH1F h2("h2","Random Histo",100,-3,3);
root [] h2->FillRandom(h,1000);
```

The distribution contained in the histogram h (TH1) is integrated over the channel contents. It is normalized to 1. Getting one random number implies:

- Generating a random number between 0 and 1 (say r1)
- Find the bin in the normalized integral for r1
- Fill histogram channel

The second parameter (1000) indicates how many random numbers are generated.

Adding, Dividing, and Multiplying

Many types of operations are supported on histograms or between histograms:

- Addition of a histogram to the current histogram
- Additions of two histograms with coefficients and storage into the current histogram
- Multiplications and Divisions are supported in the same way as additions
- The Add, Divide and Multiply functions also exist to add, divide or multiply a histogram by a function.

If a histogram has associated error bars (TH1::Sumw2 has been called), the resulting error bars are also computed assuming independent histograms. In case of divisions, binomial errors are also supported.

Projections

One can:

- Make a 1-D projection of a 2-D histogram or Profile. See functions TH2::ProjectionX, TH2::ProjectionY, TH2::ProfileX, TH2::ProfileY, TProfile::ProjectionX, TProfile2D::ProjectionXY
- Make a 1-D, 2-D or profile out of a 3-D histogram see functions TH3::ProjectionZ, TH3::Project3D.

One can fit these projections via: TH2::FitSlicesX, TH2::FitSlicesY, TH3::FitSlicesZ.

Drawing Histograms

When you call the Draw method of a histogram (TH1::Draw) for the first time, it creates a THistPainter object and saves a pointer to painter as a data member of the histogram. The THistPainter class specializes in the drawing of histograms. It is separate from the histogram so that one can have histograms without the graphics overhead, for example in a batch program. The choice to give each histogram have its own painter rather than a central singleton painter, allows two histograms to be drawn in two threads without overwriting the painter's values.

When a displayed histogram is filled again, you do not have to call the Draw method again. The image is refreshed the next time the pad is updated. A pad is updated after one of these three actions:

- A carriage control on the ROOT command line
- A click inside the pad
- A call to TPad::Update

By default, a call to TH1::Draw clears the pad of all objects before drawing the new image of the histogram. You can use the "SAME" option to leave the previous display in tact and superimpose the new histogram. The same histogram can be drawn with different graphics options in different pads.

When a displayed histogram is deleted, its image is automatically removed from the pad.

To create a copy of the histogram when drawing it, you can use TH1::DrawClone. This will clone the histogram and allow you to change and delete the original one without affecting the clone.

Setting the Style

Histograms use the current style gStyle, which is the global object of class TStyle. To change the current style for histograms, the TStyle class provides a multitude of methods ranging from setting the fill color to the axis tick marks. Here are a few examples:
When you change the current style and would like to propagate the change to a previously created histogram you can call TH1::UseCurrentStyle. You will need to call UseCurrentStyle on each histogram.

When reading many histograms from a file and you wish to update them to the current style you can use gROOT::ForceStyle and all histograms read after this call will be updated to use the current style (also see the chapter Graphics and Graphic User Interfaces).

When a histogram is automatically created as a result of a TTree::Draw, the style of the histogram is inherited from the tree attributes and the current style is ignored. The tree attributes are the ones set in the current TStyle at the time the tree was created. You can change the existing tree to use the current style, by calling TTree::UseCurrentStyle().

### Draw Options

The following draw options are supported on all histogram classes:

- **"AXIS"**: Draw only the axis
- **"HIST"**: Draw only the histogram outline (if the histogram has errors, they are not drawn)
- **"SAME"**: Superimpose on previous picture in the same pad
- **"CYL"**: Use cylindrical coordinates
- **"POL"**: Use polar coordinates
- **"SPH"**: Use spherical coordinates
- **"PSR"**: Use pseudo-rapidity/phi coordinates
- **"LEGO"**: Draw a lego plot with hidden line removal
- **"LEGO1"**: Draw a lego plot with hidden surface removal
- **"LEGO2"**: Draw a lego plot using colors to show the cell contents
- **"SURF"**: Draw a surface plot with hidden line removal
- **"SURF1"**: Draw a surface plot with hidden surface removal
- **"SURF2"**: Draw a surface plot using colors to show the cell contents
- **"SURF3"**: Same as SURF with a contour view on the top
- **"SURF4"**: Draw a surface plot using Gouraud shading

The following options are supported for 1-D histogram classes:

- **"AH"**: Draw the histogram, but not the axis labels and tick marks
- **"B"**: Draw a bar chart
- **"C"**: Draw a smooth curve through the histogram bins
- **"E"**: Draw the error bars
- **"E0"**: Draw the error bars including bins with 0 contents
- **"E1"**: Draw the error bars with perpendicular lines at the edges
- **"E2"**: Draw the error bars with rectangles
- **"E3"**: Draw a fill area through the end points of the vertical error bars
- **"E4"**: Draw a smoothed filled area through the end points of the error bars
- **"L"**: Draw a line through the bin contents
- **"P"**: Draw a (Poly) marker at each bin using the histogram's current marker style
- **"H"**: Draw histogram with a * at each bin

The following options are supported for 2-D histogram classes:

- **"ARR"**: Arrow mode. Shows gradient between adjacent cells
- **"BOX"**: Draw a box for each cell with surface proportional to contents
- **"COL"**: Draw a box for each cell with a color scale varying with contents
- **"COLZ"**: Same as "COL" with a drawn color palette
- **"CONT"**: Draw a contour plot (same as CONT0)
- **"CONTZ"**: Same as "CONT" with a drawn color palette
- **"CONT0"**: Draw a contour plot using surface colors to distinguish contours
- **"CONT1"**: Draw a contour plot using line styles to distinguish contours
- **"CONT2"**: Draw a contour plot using the same line style for all contours
- **"CONT3"**: Draw a contour plot using fill area colors
• "CONT4": Draw a contour plot using surface colors (SURF option at theta = 0)
• "LIST": Generate a list of TGraph objects for each contour
• "FB": To be used with LEGO or SURFACE, suppress the Front-Box
• "BB": To be used with LEGO or SURFACE, suppress the Back-Box
• "SCAT": Draw a scatter-plot (default)
• "TEXT": Draw cell contents as text
• \([\text{cutg}]\): Draw only the sub-range selected by the TCutG name/\("\text{cutg}\)."
• "Z": The "Z" option can be specified with the options : BOX, COL, CONT, SURF, and LEGO to display the color palette with an axis indicating the value of the corresponding color on the right side of the picture.

Most options can be concatenated without spaces or commas, for example:

```
h->Draw("E1SAME");
h->Draw("elsame");
```

The options are not case sensitive. The options BOX, COL and COLZ, use the color palette defined in the current style (see TStyle::SetPalette).

The options CONT, SURF, and LEGO have by default 20 equidistant contour levels, you can change the number of levels with TH1::SetContour.

You can also set the default drawing option with TH1::SetOption. To see the current option use TH1::GetOption.

For example:

```
h->SetOption("lego");
h->Draw(); // will use the lego option
h->Draw("scat"); // will use the scatter plot option
```

### Statistics Display

By default, drawing a histogram includes drawing the statistics box. To eliminate the statistics box use TH1::SetStats(kFALSE).

If the statistics box is drawn, you can select the type of information displayed with gStyle->SetOptStat(mode). The mode has up to seven digits that can be set to on (1) or off (0). Mode = iourmen (default = 0001111)

- \(n\) = 1 the name of histogram is printed
- \(e\) = 1 the number of entries printed
- \(m\) = 1 the mean value printed
- \(r\) = 1 the root mean square printed
- \(u\) = 1 the number of underflows printed
- \(o\) = 1 the number of overflows printed
- \(i\) = 1 the integral of bins printed

When trailing digits is left out, they are assumed 0. For example:

```
gStyle->SetOptStat(11);
```

This displays only the name of histogram and the number of entries.

When the option "same" is used, the statistic box is not redrawn; and hence the statistics from the previously drawn histogram will still show. With the option "sames", you can rename a previous "stats" box and/or change its position with these lines:

```
root[] TPaveStats *st = (TPaveStats*)gPad->GetPrimitive("stats");
root[] st->SetName(newname);
root[] st->SetX1NDC(newx1); //new x start position
root[] st->SetX1NDC(newx2); //new x end position
root[] newhist->Draw("sames");
```

### Setting Line, Fill, Marker, and Text Attributes

The histogram classes inherit from the attribute classes: TAttLine, TAttFill, TAttMarker and TAttText. See the description of these classes for the list of options.

### Setting Tick Marks on the Axis

The TPad::SetTicks method specifies the type of tick marks on the axis.

Assume \(tx = \text{gPad->GetTickx()}\) and \(ty = \text{gPad->GetTicky()}\).

- \(tx\) = 1; tick marks on top side are drawn (inside)
- \(tx\) = 2; tick marks and labels on top side are drawn
- \(ty\) = 1; tick marks on right side are drawn (inside)
- \(ty\) = 2; tick marks and labels on right side are drawn
- By default only the left Y axis and X bottom axis are drawn \((tx = ty = 0)\)

Use TPad::SetTicks(tx,ty) to set these options. See also The TAxis methods to set specific axis attributes. In case multiple color filled histograms are drawn on the same pad, the fill area may hide the axis tick marks. One can force a redraw of the axis over all the histograms by calling:

```
gPad->RedrawAxis();
```

### Giving Titles to the X, Y and Z Axis

Because the axis title is an attribute of the axis, you have to get the axis first and then call TAxis::SetTitle.

```
h->GetXaxis()->SetTitle("X axis title");
h->GetYaxis()->SetTitle("Y axis title");
```

The histogram title and the axis titles can be any TLatex string. The titles are part of the persistent histogram. For example if you wanted to write E with a subscript (T) you could use this:

```
h->GetXaxis()->SetTitle("E_T x axis title");
```

```
h->GetXaxis()->SetTitle("E_{T} ");

For a complete explanation of the LaTeX mathematical expressions see chapter "Graphics and Graphical User Interface".

### The SCATter Plot Option

By default, 2D histograms are drawn as scatter plots. For each cell (i, j) a number of points proportional to the cell content are drawn. A maximum of 500 points per cell are drawn. If the maximum is above 500 contents are normalized to 500.

### The ARRow Option

The ARR option shows the gradient between adjacent cells. For each cell (i, j) an arrow is drawn. The orientation of the arrow follows the cell gradient.

### The BOX Option

For each cell (i, j) a box is drawn with surface proportional to contents.

### The ERRor Bars Options

- **'E'** Default. Draw only the error bars, without markers.
- **'E0'** Draw also bins with 0 contents.
- **'E1'** Draw small lines at the end of the error bars.
- **'E2'** Draw error rectangles.
- **'E3'** Draw a fill area through the end points of the vertical error bars.
- **'E4'** Draw a smoothed filled area through the end points of the error bars.

### The COLor Option

For each cell (i, j) a box is drawn with a color proportional to the cell content. The color table used is defined in the current style (gStyle). The color palette in TStyle can be modified with TStyle::SetPalette.
The TEXT Option

For each cell (i, j) the cell content is printed. The text attributes are:

- Text font = current TStyle font
- Text size = 0.02* pad-height * marker-size
- Text color = marker color

The CONTour Options

The following contour options are supported:

- "CONT": Draw a contour plot (same as CONT0)
- "CONT0": Draw a contour plot using surface colors to distinguish contours
- "CONT1": Draw a contour plot using line styles to distinguish contours
- "CONT2": Draw a contour plot using the same line style for all contours
- "CONT3": Draw a contour plot using fill area colors
- "CONT4": Draw a contour plot using surface colors (SURF option at theta = 0)

The default number of contour levels is 20 equidistant levels and can be changed with TH1::SetContour.

When option "LIST" is specified together with option "CONT", the points used to draw the contours are saved in the TGraph object and are accessible in the following way:

```cpp
TObjArray *contours = gROOT->GetListOfSpecials()->FindObject("contours");
Int_t ncontours = contours->GetSize();
TList *list = (TList*)contours->At(i);
```

Where "i" is a contour number and list contains a list of TGraph objects. For one given contour, more than one disjoint poly-line may be generated. The number of TGraphs per contour is given by list->GetSize(). Here we show how to access the first graph in the list.

```cpp
TGraph *gr1 = (TGraph*)list->First();
```
The LEGO Options

In a lego plot, the cell contents are drawn as 3-d boxes, with the height of the box proportional to the cell content. A lego plot can be represented in several coordinate systems; the default system is Cartesian coordinates. Other possible coordinate systems are CYL, POL, SPH, and PSR.

- "LEGO": Draw a lego plot with hidden line removal
- "LEGO1": Draw a lego plot with hidden surface removal
- "LEGO2": Draw a lego plot using colors to show the cell contents

See TStyle::SetPalette to change the color palette. We suggest you use palette 1 with the call:

```c
gStyle->SetColorPalette(1);
```

The SURFace Options

In a surface plot, cell contents are represented as a mesh. The height of the mesh is proportional to the cell content. A surface plot can be represented in several coordinate systems. The default is Cartesian coordinates, and the other possible systems are CYL, POL, SPH, and PSR.

- "SURF": Draw a surface plot with hidden line removal
- "SURF1": Draw a surface plot with hidden surface removal
- "SURF2": Draw a surface plot using colors to show the cell contents
- "SURF3": Same as SURF with a contour view on the top
- "SURF4": Draw a surface plot using Gouraud shading

The following picture uses SURF1. See TStyle::SetPalette to change the color palette. We suggest you use palette 1 with the call:

```c
gStyle->SetColorPalette(1);
```
The BAR options

When the option "bar" or "hbar" is specified, a bar chart is drawn.

Vertical BAR chart

The options are "bar", "bar0", "bar1", "bar2", "bar3", "bar4".
- The bar is filled with the histogram fill color.
- The left side of the bar is drawn with a light fill color.
- The right side of the bar is drawn with a dark fill color.
- The percentage of the bar drawn with either the light or dark color is:
  - 0 per cent for option "bar" or "bar0"
  - 10 per cent for option "bar1"
  - 20 per cent for option "bar2"
  - 30 per cent for option "bar3"
  - 40 per cent for option "bar4"

Use TH1::SetBarWidth to control the bar width (default is the bin width)
Use TH1::SetBarOffset to control the bar offset (default is 0)
See example in $ROOTSYS/tutorials/hbars.C

Horizontal BAR chart:

The options for the horizontal bar chart are:
- "hbar", "hbar0", "hbar1", "hbar2", "hbar3", "hbar4"
- A horizontal bar is drawn for each bin.
- The bar is filled with the histogram fill color.
- The bottom side of the bar is drawn with a light fill color.
- The top side of the bar is drawn with a dark fill color.
- The percentage of the bar drawn with either the light or dark color is:
  - 0 per cent for option "hbar" or "hbar0"
  - 10 per cent for option "hbar1"
  - 20 per cent for option "hbar2"
  - 30 per cent for option "hbar3"
  - 40 per cent for option "hbar4"

Use TH1::SetBarWidth to control the bar width (default is the bin width)
Use TH1::SetBarOffset to control the bar offset (default is 0)
See example in $ROOTSYS/tutorials/hbars.C

The Z Option: Display the Color Palette on the Pad

The "Z" option can be specified with the options: BOX, COL, CONT, SURF, and LEGO to display the color palette with an axis indicating the value of the corresponding color on the right side of the picture.

If there is not enough space on the right side, you can increase the size of the right margin by calling TPad::SetRightMargin.
The attributes used to display the palette axis values are taken from the Z axis of the object. For example, you can set the labels size on the palette axis with:

```cpp
hist->GetZaxis()->SetLabelSize();
```

### Setting the color palette

You can set the color palette with `TStyle::SetPalette`, e.g.

```cpp
gStyle->SetPalette(ncolors,colors);
```

For example, the option `COL` draws a 2-D histogram with cells represented by a box filled with a color index, which is a function of the cell content. If the cell content is N, the color index used will be the color number in `colors[N]`. If the maximum cell content is greater than `ncolors`, all cell contents are scaled to `ncolors`.

If `ncolors <= 0`, a default palette (see below) of 50 colors is defined. This palette is recommended for pads, labels.

If `ncolors == 1 && colors == 0`, a pretty palette with a violet to red spectrum is created. We recommend you use this palette when drawing lego plots, surfaces, or contours.

If `ncolors > 0 && colors == 0`, the default palette is used with a maximum of `ncolors`.

The default palette defines:

- Index 0 to 9: shades of gray
- Index 10 to 19: shades of brown
- Index 20 to 29: shades of blue
- Index 30 to 39: shades of red
- Index 40 to 49: basic colors

The color numbers specified in the palette can be viewed by selecting the item "colors" in the "VIEW" menu of the canvas toolbar. The color's red, green, and blue values can be changed via `TColor::SetRGB`.

### Drawing a Sub-range of a 2-D Histogram (the [cutg] Option)

Using a `TCutG` object, it is possible to draw a sub-range of a 2-D histogram. One must create a graphical cut (mouse or C++) and specify the name of the cut between `[]` in the Draw option.

For example, with a `TCutG` named "cutg", one can call:

```cpp
myHist->Draw("surf1 [cutg]");
```

Or, assuming two graphical cuts with name "cut1" and "cut2", one can do:

```cpp
h1.Draw("lego");
h2.Draw("[cut1,-cut2],surf,same");
```

The second `Draw` will superimpose on top of the first lego plot a subset of `h2` using the "surf" option with:

- all the bins inside cut1
- all the bins outside cut2

Up to 16 cuts may be specified in the cut string delimited by "[..]". Currently only the following drawing options are sensitive to the cuts option: `col`, `box`, `scat`, `hist`, `lego`, `surf` and `cartesian` coordinates only.

See a complete example in the tutorial `$ROOTSYS/tutorials/fit2a.C`.

This tutorial produces the following picture:

### Drawing Options for 3-D Histograms

By default a 3-d scatter plot is drawn. If the "BOX" option is specified, a 3-D box with a volume proportional to the cell content is drawn.
Superimposing Histograms with Different Scales

The following script creates two histograms; the second histogram is the bins integral of the first one. It shows a procedure to draw the two histograms in the same pad and it draws the scale of the second histogram using a new vertical axis on the right side.

```c
void twoscales() {
    TCanvas *c1 = new TCanvas("c1","hists with different scales",600,400);
    //create, fill and draw h1
    gStyle->SetOptStat(kFALSE);
    TH1F *h1 = new TH1F("h1","my histogram",100,-3,3);
    Int_t i;
    for (i=0;i<10000;i++) h1->Fill(gRandom->Gaus(0,1));
    h1->Draw();
    c1->Update();
    //create hint1 filled with the bins integral of h1
    TH1F *hint1 = new TH1F("hint1","h1 bins integral",100,-3,3);
    Float_t sum = 0;
    for (i=1;i<=100;i++) {
        sum += h1->GetBinContent(i);
        hint1->SetBinContent(i,sum);
    }
    //scale hint1 to the pad coordinates
    Float_t rightmax = 1.1*hint1->GetMaximum();
    Float_t scale = gPad->GetUymax()/rightmax;
    hint1->SetLineColor(kRed);
    hint1->Scale(scale);
    hint1->Draw("same");
    //draw an axis on the right side
    TAxis *axis = new TAxis(gPad->GetUxmax(),gPad->GetUymin(),gPad->GetUxmax(),
            gPad->GetUymin(),0,rightmax,510,"+L");
    axis->SetLineColor(kRed);
    axis->SetTextColor(kRed);
    axis->Draw();
}
```

Making a Copy of an Histogram

Like for any other ROOT object derived from TObject, one can use the `Clone` method. This makes an identical copy of the original histogram including all associated errors and functions:

```c
TH1 *hnew = (TH1*)h->Clone();
hnew->SetName("hnew");
// renaming is recommended, because otherwise you will
// have 2 histograms with the same name.
```

Normalizing Histograms

You can scale a histogram (TH1 *h) such that the bins integral is equal to the normalization parameter norm with:

```c
Double_t scale = norm/h->Integral();
h->Scale(scale);
```

Saving/Reading Histograms to/from a file

The following statements create a ROOT file and store a histogram on the file. Because TH1 derives from TNamed, the key identifier on the file is the histogram name:

```c
TFile f("histos.root","new");
TH1 h1("hgaus","histo from a gaussian",100,-3,3);
h1.FillRandom("gaus",10000);
h1->Write();
To read this histogram in another ROOT session, do:
TFile f("histos.root");
TH1 *h = (TH1*)f.Get("hgaus");
```

One can save all histograms in memory to the file by:

```c
file->Write();
```

For a more detailed explanation, see chapter Input/Output.

Miscellaneous Operations

- TH1::KolmogorovTest(): statistical test of compatibility in shape between two histograms.
- TH1::Smooth(): smoothes the bin contents of a 1-d histogram
- TH1::Integral: returns the integral of bin contents in a given bin range
• TH1::GetMean(int axis): returns the mean value along axis
• TH1::GetRMS(int axis): returns the Root Mean Square along axis
• H1::GetEntries (): returns the number of entries
• TH1::Reset(): resets the bin contents and errors of a histogram

Alphanumeric Bin Labels

By default, a histogram axis is drawn with its numeric bin labels. One can specify alphanumeric labels instead.

**Option 1: SetBinLabel**

To set an alphanumeric bin label call:

```cpp
TAxis::SetBinLabel(bin, label);
```

This can always be done before or after filling. When the histogram is drawn, bin labels will be automatically drawn.

**Option 2: Fill**

You can also call a `Fill` function with one of the arguments being a string:

```cpp
hist1->Fill(somename, weight);
hist2->Fill(x, somename, weight);
hist2->Fill(somename, y, weight);
hist2->Fill(somenamex, somenamemy, weight);
```

See example in `$ROOTSYS/tutorials/hlabels1.C`, `hlabels2.C`.

**Option 3: TTree::Draw**

You can use a `char` variable type to histogram strings with `TTree::Draw`.

```cpp
tree.Draw("Nation::Division");
// where "Nation" and "Division" are two char*
// branches of a TTree.
```

There is an example in `$ROOTSYS/tutorials/cernstaff.C`.

If a variable is defined as `char*` it is drawn as a string by default. You change that and draw the value of `char[0]` as an integer by adding an arithmetic operation to the expression as shown below.

```cpp
tree.Draw("MyChar + 0");
// this will draw the integer value of MyChar[0]
// where "MyChar" is char[5]
```

**Sort Options**

When using the options 2 or 3 above, the labels are automatically added to the list (THashList) of labels for a given axis. By default, an axis is drawn with the order of bins corresponding to the filling sequence. It is possible to reorder the axis alphabetically or by increasing or decreasing values.

The reordering can be triggered via the `TAxis` context menu by selecting the menu item "LabelsOption" or by calling directly.

```cpp
TH1::LabelsOption(option, axis)
```

Where `axis` may be "X", "Y" or "Z"

- "a" sort by alphabetic order
- "<" sort by decreasing values
- ">" sort by increasing values
- "H" draw labels horizontal
- "V" draw labels vertical
- "U" draw labels up (end of label right adjusted)
- "D" draw labels down (start of label left adjusted)
When using the option 2 above, new labels are added by doubling the current number of bins in case one label does not exist yet. When the Filling is terminated, it is possible to trim the number of bins to match the number of active labels by calling:

\[
\text{TH1::LabelsDeflate}(\text{axis})
\]

Where \(\text{axis} = \text{"X"}, \text{"Y"} \text{ or "Z"} \)

This operation is automatic when using \text{TTree::Draw}.

Once bin labels have been created, they become persistent if the histogram is written to a file or when generating the C++ code via \text{SavePrimitive}.

### Histogram Stacks

A \text{THStack} is a collection of \text{TH1} (or derived) objects. To add a histogram to the stack use \text{THStack::Add(TH1 *h)}. The \text{THStack} owns the objects in the list.

By default, \text{THStack::Draw} draws the histograms stacked as shown in the left pad in the picture above. If the option \text{"nostack"} is used, the histograms are superimposed as if they were drawn one at a time using the \text{"same"} draw option. The right pad in the picture above illustrates the \text{THStack} drawn with the \text{"nostack"} option.

### Profile Histograms

Profile histograms are in many cases an elegant replacement of two-dimensional histograms. The relationship of two quantities \(X\) and \(Y\) can be visualized by a two-dimensional histogram or a scatter-plot. Its representation is not particularly satisfactory, except for sparse data. If \(Y\) is an unknown (but single-valued) function of \(X\), it can be displayed by a profile histogram with much better precision than by a scatter-plot. Profile histograms display the mean value of \(Y\) and its RMS for each bin in \(X\).

The following shows the contents (capital letters) and the values shown in the graphics (small letters) of the elements for bin \(j\).

When you fill a profile histogram with \text{TProfile.Fill(x,y)}:

- \(E[j]\) contains for each bin \(j\) the sum of the \(y\) values for this bin.
- \(L[j]\) contains the number of entries in the bin \(j\).

\(e[j]\) or \(s[j]\) will be the resulting error depending on the selected option described in Build Options below.

\[
\begin{align*}
E[j] & = \text{sum } \text{Y} \\
L[j] & = \text{number of entries in bin } j \\
h[j] & = \text{H[j] / L[j]} \\
e[j] & = s[j] / \text{sqrt}[L[j]]
\end{align*}
\]

In the special case where \(s[j]\) is zero, when there is only one entry per bin, \(e[j]\) is computed from the average of the \(s[j]\) for all bins. This approximation is used to keep the bin during a fit operation.

#### THStack Example:

Here is a simple example, for a more complex example in $ROOTSYS/tutorials/hstack.C.

```cpp
{ 
    THStack hs("hs","test stacked histograms");
    TH1F *h1 = new TH1F("h1","test hstack",100,-4,4);
    h1->FillRandom("gaus",20000);
    h1->SetFillColor(kRed);
    hs.Add(h1);
    TH1F *h2 = new TH1F("h2","test hstack",100,-4,4);
    h2->FillRandom("gaus",15000);
    h2->SetFillColor(kBlue);
    hs.Add(h2);
    TH1F *h3 = new TH1F("h3","test hstack",100,-4,4);
    h3->FillRandom("gaus",10000);
    h3->SetFillColor(kGreen);
    hs.Add(h3);
    TCanvas c1("c1","stacked hists",10,10,700,900);
    c1.Divide(1,2);
    c1.cd(1);
    hs.Draw();
    c1.cd(2);
    hs->Draw("nostack");
}
```
The TProfile Constructor

The TProfile constructor takes up to six arguments. The first five parameters are similar to TH1::TH1.

```c
TProfile(const char *name, const char *title, Int_t nbins, Axis_t xlow, Axis_t xup, Option_t *option)
```

The first five parameters are similar to TH1::TH1. All values of \( y \) are accepted at filling time. To fill a profile histogram, you must use TProfile::Fill function.

Note that when filling the profile histogram the method TProfile::Fill checks if the variable \( y \) is between \( fYmin \) and \( fYmax \). If a minimum or maximum value is set for the \( y \) scale before filling, then all values below \( y \) or above \( y \) will be discarded. Setting the minimum or maximum value for the \( y \) scale before filling has the same effect as calling the special TProfile constructor above where \( ymin \) and \( ymax \) are specified.

Build Options

The last parameter is the build option. If a bin has \( N \) data points all with the same value \( Y \), which is the case when dealing with integers, the spread in \( Y \) for that bin is zero, and the uncertainty assigned is also zero, and the bin is ignored in making subsequent fits. If \( SQRT(Y) \) was the correct error in the case above, then \( SQRT(Y)/SQRT(N) \) would be the correct error here. In fact, any bin with non-zero number of entries \( N \) but with zero spread should have an uncertainty \( SQRT(Y)/SQRT(N) \).

Now, is \( SQRT(Y)/SQRT(N) \) really the correct uncertainty? That it is only in the case where the \( Y \) variable is some sort of counting statistics, following a Poisson distribution. This is the default case. However, \( Y \) can be any variable from an original NTUPLE, and does not necessarily follow a Poisson distribution.

The computation of errors is based on the parameter option:

\( Y = \) values of data points
\( N = \) number of data points

- `'` The default is blank, the Errors are:
  - spread/SQRT(N) for a non-zero spread
  - SQRT(Y)/SQRT(N) for a spread of zero and some data points
  - 0 for no data points

- `'s` Errors are:
  - spread for a non-zero spread
  - SQRT(Y) for a spread of zero and some data points
  - 0 for no data points

- `'i` Errors are:
  - spread/SQRT(N) for a non-zero spread
  - 1/SQRT(12*N) for a spread of zero and some data points
  - 0 for no data points

- `'g` Errors are:
  - spread/SQRT(N) for a non-zero spread
  - sigma/SQRT(N) for a spread of zero and some data points
  - 0 for no data points

The third case (option `'i`) is used for integer \( Y \) values with the uncertainty of +/-0.5, assuming the probability that \( Y \) takes any value between \( Y-0.5 \) and \( Y+0.5 \) is uniform (the same argument for \( Y \) uniformly distributed between \( Y \) and \( Y+1 \)). An example is an ADC measurement.

Example of a TProfile

Here is a simple example of a profile histogram with its graphic output:

```c
{ // Create a canvas giving the coordinates and the size
  TCanvas *c1 = new TCanvas
    ("c1","Profile example",200,10,700,500);
  // Create a profile with the name, title, the number of bins, the low and high limit of the x-axis and the low and high limit of the y-axis. No option is given so the default is used.
  hprof = new TProfile
    ("hprof","Profile of pz versus px",100,-4,4,0,20);
  // Fill the profile 25000 times with random numbers
  Float_t px, py, pz;
  for ( Int_t i=0; i<25000; i++)
    { // Use the random number generator to get two numbers following a gaussian distribution
      // with mean=0 and sigma=1
      gRandom->Rannor(px,py);
      pz = px*px + py*py;
      hprof->Fill(px,pz,1);
    }
  hprof->Draw();
}
```
Drawing a Profile without Error Bars
To draw a profile histogram and not show the error bars use the "HIST" option in the TProfile::Draw method. This will draw the outline of the TProfile.

Create a Profile from a 2D Histogram
You can make a profile from a histogram using the methods TH2::ProfileX and TH2::ProfileY.

Create a Histogram from a Profile
To create a regular histogram from a profile histogram, use the method TProfile::ProjectionX. This example instantiates a TH1D object by copying the TH1D piece of a TProfile.

You can do the same with a 2D profile with the TProfile2D::ProjectionX method.

Generating a Profile from a TTree
The 'prof' and 'profs' options in the TTree::Draw method (see the chapter on Trees) generate a profile histogram (TProfile), given a two dimensional expression in the tree, or a TProfile2D given a three dimensional expression.

Note that you can specify 'prof' or 'profs': 'prof' generates a TProfile with error on the mean, 'profs' generates a TProfile with error on the spread.

2D Profiles
The class for a 2D Profile is called TProfile2D. It is in many cases an elegant replacement of a three-dimensional histogram. The relationship of three measured quantities X, Y and Z can be visualized by a three-dimensional histogram or scatter-plot; its representation is not particularly satisfactory, except for sparse data. If Z is an unknown (but single-valued) function of X,Y, it can be displayed with a TProfile2D with better precision than by a scatter-plot.

A TProfile2D displays the mean value of Z and its RMS for each cell in X,Y.

When you fill a profile histogram with TProfile2D.Fill[x,y,z]:
E[i,j] will contain for each bin [i,j] the sum of the z values for this bin
L[i,j] contains the number of entries in the bin
s[i,j] or e[i,j] will be the resulting error depending on the selected option described in Build Options above.

\[
E_{i,j} = \sum z \\
L_{i,j} = \sum i \\
H_{i,j} = E_{i,j}/L_{i,j} \\
s_{i,j} = \sqrt{(E_{i,j}/L_{i,j})^2 - H_{i,j}^2} \\
e_{i,j} = s_{i,j} / \sqrt{L_{i,j}}
\]
4 Graphs

A graph is a graphics object made of two arrays X and Y, holding the x, y coordinates of n points. There are several graph classes, they are: TGraph, TGraphErrors, TGraphAsymmErrors, and TMultiGraph.

TGraph

The TGraph class supports the general case with non equidistant points, and the special case with equidistant points.

Creating Graphs

Graphs are created with the constructor. Here is an example. First we define the arrays of coordinates and then create the graph. The coordinates can be arrays of doubles or floats.

```cpp
Int_t n = 20;
Double_t x[n], y[n];
for (Int_t i=0;i<n;i++) {
    x[i] = i*0.1;
    y[i] = 10*sin(x[i]+0.2);
}
TGraph * gr1 = new TGraph (n, x, y);
```

An alternative constructor takes only the number of points (n). It is expected that the coordinates will be set later.

```cpp
TGraph *gr2 = new TGraph(n);
```

Graph Draw Options

The various draw options for a graph are explained in TGraph::PaintGraph. They are:

- "L" A simple poly-line between every points is drawn
- "F" A fill area is drawn
- "A" Axis are drawn around the graph
- "C" A smooth curve is drawn
- "*" A star is plotted at each point
- "$P$" The current marker of the graph is plotted at each point
- "$B$" A bar chart is drawn at each point
- "[" Only the end vertical/horizontal lines of the error bars are drawn. This option only applies to the TGraphAsymmErrors.

The options are not case sensitive and they can be concatenated in most cases. Let's look at some examples.

Continuous line, Axis and Stars (AC*)

```cpp
int_t n = 20;
double x[n], y[n];
for (int_t i=0;i<n;i++) {
    x[i] = i*0.1;
    y[i] = 10*sin(x[i]+0.2);
}
// create graph
TGraph *gr = new TGraph(n,x,y);
TCanvas *c1 = new TCanvas("c1","Graph Draw Options", 200, 10, 600, 400);
// draw the graph with axis, continuous line, and put a * at each point
gr->Draw("AC*");
```
Bar Graphs (AB)

```
TGraph *gr1 = new TGraph(n,x,y);
gr1->SetFillColor(40);
gr1->Draw("AB");
```

This code will only work if n, x, and y is defined. The previous example defines these.
You need to set the fill color, because by default the fill color is white and will not be visible on a white canvas. You also need to give it an axis, or the bar chart will not be displayed properly.

Filled Graphs (AF)

```
TGraph *gr3 = new TGraph(n,x,y);
gr3->SetFillColor(45);
gr3->Draw("AF");
```

This code will only work if n, x, and y is defined. The first example defines these.
You need to set the fill color, because by default the fill color is white and will not be visible on a white canvas. You also need to give it an axis, or the bar chart will not be displayed properly.

Currently one can not specify the "CF" option.

Marker Options

```
{ 
Int_t n = 20;
Double_t x[n], y[n];

// build the arrays with the coordinate of points
for (Int_t i=0;i<n;i++) {
x[i] = i*0.1;
y[i] = 10*sin(x[i]+0.2);
}

// create graphs
TGraph *gr3 = new TGraph(n,x,y);
TCanvas *c1 = new TCanvas("c1","Graph Draw Options",200,10,600,400);

draw the graph with the axis,continuous line, and put a marker using the graph's marker style at each point
gr3->SetMarkerStyle(21);
c1->cd(4);
gr3->Draw("APL");

draw the graph with the axis,continuous line, and put a marker using the graph's marker style at each point
gr3->SetMarkerStyle(21);
c1->cd(4);
gr3->Draw("APL");

g3->SetMarkerSize(2);
g3->SetMarkerColor(31+j);
g3->Draw();
}
```

This code will only work if n, x, and y is defined. The previous example defines these.
You need to set the fill color, because by default the fill color is white and will not be visible on a white canvas. You also need to give it an axis, or the bar chart will not be displayed properly.
Superimposing two Graphs

To superimpose two graphs you need to draw the axis only once, and leave out the "A" in the draw options for the second graph. Here is an example:

```cpp
{ 
    gROOT->Reset();
    Int_t n = 20;
    Double_t x[n], y[n], x1[n], y1[n];
    // create the blue graph with a cos function
    for (Int_t i=0;i<n;i++) {
        x[i] = i*0.5;
        y[i] = 5*cos(x[i]+0.2);
        x1[i] = i*0.5;
        y1[i] = 5*sin(x[i]+0.2);
    }
    TGraph *gr1 = new TGraph(n,x,y);
    TGraph *gr2  = new TGraph(n,x1,y1);
    TCanvas *c1 = new TCanvas("c1","Two Graphs", 200, 10, 600, 400);
    // draw the graph with axis, continuous line, and put a * at each point
    gr1->SetLineColor(4);
    gr1->Draw("AC*");
    // superimpose the second graph by leaving out the axis option "A"
    gr2->SetLineWidth(3);
    gr2->SetMarkerStyle(21);
    gr2->SetLineColor(2);
    gr2->Draw("CP");
}
```

TGraphErrors

A TGraphErrors is a TGraph with error bars. The various format options to draw a TGraphErrors are the same for TGraph. In addition, it can be drawn with the "Z" option to leave off the small lines at the end of the error bars.

The constructor has four arrays as parameters. X and Y as in TGraph and X- and Y-errors the size of the errors in the x and y direction.

This example is in $ROOTSYS/tutorials/gerrors.C.

```cpp
{ 
    gROOT->Reset();
    c1 = new TCanvas("c1","A Simple Graph with error bars",200,10,700,500);
    c1->SetFillColor(42);
    c1->SetGrid();
    c1->GetFrame()->SetFillColor(21);
    c1->GetFrame()->SetBorderSize(12);
    // create the coordinate arrays
    Int_t n = 10;
    Float_t x[n]  = {-.22,.05,.25,.35,.5,.61,.7,.85,.89,.95};
    Float_t y[n]  = {1,2.9,5.6,7.4,9,9.6,8.7,6.3,4.5,1};
    Float_t ex[n] = {.05,.1,.07,.07,.04,.05,.06,.07,.08,.05};
    Float_t ey[n] = {.8,.7,.6,.5,.4,.4,.5,.6,.7,.8};
    // create the error arrays
    Float_t ex[n] = {.05,.1,.07,.07,.04,.05,.06,.07,.08,.05};
    Float_t ey[n] = {.8,.7,.6,.5,.4,.4,.5,.6,.7,.8};
    // create the TGraphErrors and draw it
    gr = new TGraphErrors(n,x,y,ex,ey);
    gr->SetTitle("TGraphErrors Example");
    gr->SetMarkerColor(4);
    gr->SetMarkerStyle(21);
    gr->Draw("ALP");
    c1->Update();
}
```
**TGraphAsymmErrors**

A TGraphAsymmErrors is a TGraph with asymmetric error bars. The various format options to draw a TGraphAsymmErrors are as for TGraph.

The constructor has six arrays as parameters: X and Y as TGraph and low X-errors and high X-errors, low Y-errors and high Y-errors. The low value is the length of the error bar to the left and down, the high value is the length of the error bar to the right and up.

```c
// create the arrays for the points
Int_t n = 10;
Double_t x[n] = {-.22,.05,.25,.35,.5,.61,.7,.85,.89,.95};
Double_t y[n] = {1,2.9,5.6,7.4,9,9.6,8.7,6.3,4.5,1};
Double_t exl[n] = {.05,.1,.07,.07,.04,.05,.06,.07,.08,.05};
Double_t eyl[n] = {.8,.7,.6,.5,.4,.4,.5,.6,.7,.8};
Double_t exh[n] = {.02,.08,.05,.03,.03,.04,.05,.06,.03};
Double_t eyh[n] = {.6,.5,.4,.3,.2,.3,.4,.5,.6};

// create TGraphAsymmErrors with the arrays
gr = new TGraphAsymmErrors(n,x,y,exl,exh,eyl,eyh);
```

**Fitting a Graph**

The Fit method of the graph works the same as the TH1::Fit (see Fitting Histograms).

```c
// create the points
Int_t n = 10;
Double_t x[n] = {-.22,.05,.25,.35,.5,.61,.7,.85,.89,.95};
Double_t y[n] = {1,2.9,5.6,7.4,9,9.6,8.7,6.3,4.5,1};

// create the width of errors in x and y direction
Double_t wx[n] = {.05,.1,.07,.05,.06,.07,.08,.05};
Double_t wy[n] = {.8,.7,.6,.5,.4,.4,.5,.6,.7,.8};

// create two graphs
TGraph *gr1 = new TGraph(n,x,y);
TGraphErrors *gr2 = new TGraphErrors(n,x,y,wx,wy);

// create a multigraph and draw it
TMultiGraph *mg = new TMultiGraph();
mg->Add(gr1);
mg->Add(gr2);
mg->Draw("ALP");
```
Setting the Graph's Axis Title

To give the axis of a graph a title you need to draw the graph first, only then does it actually have an axis object. Once drawn, you set the title by getting the axis and calling the `TAxis::SetTitle` method, and if you want to center it you can call the `TAxis::CenterTitle` method.

Assuming that \( n, x, \) and \( y \) are defined, this code sets the titles of the x and y axes.

```c
root[] gr5 = new TGraph(n,x,y);
root[] gr5->Draw();
<TCanvas::MakeDefCanvas>: created default TCanvas with name c1
root[] gr5->Draw("ALP")
root[] gr5->GetXaxis()->SetTitle("X-Axis")
root[] gr5->GetYaxis()->SetTitle("Y-Axis")
root[] gr5->GetXaxis()->CenterTitle()
root[] gr5->GetYaxis()->CenterTitle()
root[] gr5->Draw("ALP")
```

For more graph examples see: these scripts in the `$ROOTSYS/tutorials` directory `graph.C`, `gerrors.C`, `zdemo.C`, and `gerrors2.C`.

Zooming a Graph

To zoom a graph you can create a histogram with the desired axis range first. Draw the empty histogram and then draw the graph using the existing axis from the histogram.

The example below is the same graph as above with a zoom in the x and y direction.

```c
{ 
grROOT->Reset();
c1 = new TCanvas("c1", "A Zoomed Graph", 200,10,700,500);
// create a histogram for the axis range
hpx = new TH2F("hpx", "Zoomed Graph Example", 10, 0.05,10.0,8.0);
// no statistics
hpx->SetStats(kFALSE);
hpx->Draw();
// create a graph
Int_t n = 10;
Double_t x[n] = {-.22,.05,.25,.35,.5,.61,.7,.85,.89,.95};
Double_t y[n] = {1,2.9,5.6,7.4,9,9.6,8.7,6.3,4.5,1};
gr = new TGraph(n,x,y);
gr->SetTitle("Y-Axis");
gr->SetMarkerColor(4);
gr->SetMarkerStyle(20);
// and draw it without an axis
gr->Draw("LP"); }```
5 Fitting Histograms

To fit a histogram you can use the Fit Panel on a visible histogram using the GUI, or you can use the TH1::Fit method. The Fit Panel, which is limited, is best for prototyping. The histogram needs to be drawn in a pad before the Fit Panel is available. The TH1::Fit method is more powerful and used in scripts and programs.

The Fit Panel

To display the Fit Panel right click on a histogram to bring up the context menu, then select the menu option: FitPanel.

The first sets of buttons are the predefined functions of ROOT that can be used to fit the histogram. You have a choice of several polynomials, a gaussian, a landau, and an exponential function. You can also define a function and call it "user". It will be linked to the user button on this panel.

You have the option to specify Quiet or Verbose. This is the amount of feedback printed on the root command line on the result of the fit.

When a fit is executed the image of the function is drawn on the current pad. By default the image of the histogram is replaced with the image of the function. You can select Same Picture to see the function drawn and the histogram on the same picture.

Select W: Set all weights to 1, to set all errors to 1.

Select E: Compute best errors to use the Minos technique to compute best errors.

Select N: Do not store/draw function to avoid adding the function to the histogram and to avoid drawing it.

Select 0: Do not draw function to avoid drawing the result of the fit.

Select L: Log Likelihood to use log likelihood method (default is chi-square method).

The slider at the bottom of the panel allows you to set a range for the fit. Drag the edges of the slider towards the center to narrow the range. Draw the entire range to change the beginning and end.

To return to the original setting, you need press Defaults.

To apply the fit, press the Fit button.

The Fit Method

To fit a histogram programmatically, you can use the TH1::Fit method. Here is the signature of TH1::Fit and an explanation of the parameters:

```cpp
void Fit(const char *fname , Option_t *option , Option_t *goption, Axis_t xxmin,  Axis_t xxmax)
```

- *fname*: The name of the fitted function (the model) is passed as the first parameter. This name may be one of the of ROOT's pre-defined function names or a user-defined function.

- **gaus**: A gaussian function with 3 parameters:
  
  \[ f(x) = p0*exp(-0.5*(x-p1)/p2)^2) \]

- **expo**: An exponential with 2 parameters:
  
  \[ f(x) = exp(p0+p1*x) \]

- **polN**: A polynomial of degree N:
  
  \[ f(x) = p0 + p1*x + p2*x^2 +... \]

- **landau**: A landau function with mean and sigma. This function has been adapted from the CERNLIB routine G110 denlan.

- **option**: The second parameter is the fitting option. Here is the list of fitting options:
  - "W" Set all errors to 1
  - "I" Use integral of function in bin instead of value at bin center
  - "L" Use loglikelihood method (default is chi-square method)
  - "U" Use a user specified fitting algorithm
  - "Q" Quiet mode (minimum printing)
  - "V" Verbose mode (default is between Q and V)
  - "E" Perform better errors estimation using Minos technique
  - "M" Improve fit results
  - "R" Use the range specified in the function range
  - "N" Do not store the graphics function, do not draw
  - "0" Do not plot the result of the fit. By default the fitted function is drawn unless the option "N" above is specified.
  - "+" Add this new fitted function to the list of fitted functions (by default, the previous function is deleted and only the last one is kept)
  - "B" Disable the automatic computation of the initial parameter values for the standard functions like poln, expo, and gaus.

- **goption**: The third parameter is the graphics option (goption), it is the same as in the TH1::Draw (see Draw Options above).
xxmin, xxmax: The fourth and fifth parameters specify the range over which to apply the fit. By default, the fitting function object is added to the histogram and is drawn in the current pad.

**Fit with a Predefined Function**

To fit a histogram with a predefined function, simply pass the name of the function in the first parameter of TH1::Fit. For example, this line fits histogram object hist with a gaussian.

```
root[] hist.Fit("gaus");
```

For pre-defined functions, there is no need to set initial values for the parameters, it is done automatically.

**Fit with a User-Defined Function**

You can create a TF1 object and use it in the call to TH1::Fit. The parameter in the Fit method is the NAME of the TF1 object.

There are three ways to create a TF1.
1. Using C++ like expression using x with a fixed set of operators and functions defined in TFormula.
2. Same as #1, with parameters.
3. Using a function that you have defined

**Creating a TF1 with a Formula**

Let's look at the first case. Here we call the TF1 constructor by giving it the formula: \( \sin(x)/x \).

```
root[] TF1 *f1 = new TF1("f1", "sin(x)/x", 0,10)
```

You can also use a TF1 object in the constructor of another TF1.

```
root[] TF1 *f2 = new TF1("f1 * 2", "f1 * 2", 0,10)
```

**Creating a TF1 with Parameters**

The second way to construct a TF1 is to add parameters to the expression. For example, this TF1 has 2 parameters:

```
root[] TF1 *f3 = new TF1("f3", "[0]*sin([1]*x)", -3,3);
```

The parameter index is enclosed in square brackets. To set the initial parameters explicitly you can use the SetParameter method.

```
root[] f3->SetParameter(0,10);
```

This sets parameter 0 to 10. You can also use SetParameters to set multiple parameters at once.

```
root[] f3->SetParameters(10,5);
```

This sets parameter 0 to 10 and parameter 1 to 5. We can now draw the TF1:

```
root[] f3->Draw();
```

**Creating a TF1 with a User Function**

The third way to build a TF1 is to define a function yourself and then give its name to the constructor. A function for a TF1 constructor needs to have this exact signature:

```
Double_t fitf(Double_t *x, Double_t *par)
```

The two parameters are:

- **Double_t *x**: a pointer to the dimension array. Each element contains a dimension. For a 1D histogram only x[0] is used, for a 2D histogram x[0] and x[1] is used, and for a 3D histogram x[0], x[1], and x[2] are used. For histograms, only 3 dimensions apply, but this method is also used to fit other objects, for example an ntuple could have 10 dimensions.
- **Double_t *par**: a pointer to the parameters array. This array contains the current values of parameters when it is called by the fitting function.

The following script $ROOTSYS/tutorials/myfit.C illustrates how to fit a 1D histogram with a user-defined function. First we declare the function.

```
// define a function with 3 parameters
Double_t fitf(Double_t *x, Double_t *par)
{
  Double_t arg = 0;
  if (par[2]) arg = (x[0] - par[1])/par[2];
  Double_t fitval = par[0]*TMath::Exp(-0.5*arg*arg);
  return fitval;
}
```
Now we use the function:

```c
// this function used fitf to fit a histogram
void fitexample()
{
  // open a file and get a histogram
  TFile *f = new TFile("hsimple.root");
  TF1 *hpx = (TF1*)f->Get("hpx");
  // create a TF1 object using the function defined above.
  // The last 3 specifies the number of parameters
  // for the function.
  TF1 *func = new TF1("fit", fitf, -3, 3, 3);
  // set the parameters to the mean and RMS of the histogram
  func->SetParameters(500, hpx->GetMean(), hpx->GetRMS());
  // give the parameters meaningful names
  func->SetParNames("Constant", "Mean_value", "Sigma");
  // call TH1::Fit with the name of the TF1 object
  hpx->Fit("fit");
}
```

### Fixing and Setting Bounds for Parameters

Parameters must be initialized before invoking the `Fit` method. The setting of the parameter initial values is automatic for the predefined functions: `poln`, `exp`, `gaus`. You can disable the automatic computation by specifying the "B" option when calling the `Fit` method.

When a function is not predefined, the fit parameters must be initialized to some value as close as possible to the expected values before calling the fit function.

To set bounds for one parameter, use `TF1::SetParLimits`:

```c
func->SetParLimits(0, -1, 1);
```

When the lower and upper limits are equal, the parameter is fixed. This statement fixes parameter 4 at 10.

```c
func->SetParameter(4,10)
func->SetParLimits(4,77,77);
```

However, to fix a parameter to 0, one must call the `FixParameter` function:

```c
func->FixParameter(4,0);
```

Note that you are not forced to fix the limits for all parameters. For example, if you fit a function with 6 parameters, you can:

```c
func->SetParameters(0,3,1,1.e-6,-1.5,0,100);
func->SetParLimits(3,-10,-4);
func->FixParameter(4,0);
```

With this setup, parameters 0 to 2 can vary freely, parameter 3 has boundaries [-10,-4] with initial value -8, and parameter 4 is fixed to 0.

### Fixing Sub Ranges

By default, `TH1::Fit` will fit the function on the defined histogram range. You can specify the option "R" in the second parameter of `TH1::Fit` to restrict the fit to the range specified in the `TF1` constructor. In this example, the fit will be limited to -3 to 3, the range specified in the `TF1` constructor.

```c
root[] TFile *f1 = new TFile("f1","[0]*x*sin([1]*x)","-3,3");
root[] hist->Fit("f1", "R");
```

You can also specify a range in the call to `TH1::Fit`:

```c
root[] hist->Fit("f1","[0]*x*sin([1]*x)","-2,2");
```

For more complete examples, see `$ROOTSYS/tutorials/myfit.C` and `$ROOTSYS/tutorials/multifit.C`.

### Example: Fitting Multiple Sub Ranges

The script for this example is in `$ROOTSYS/tutorials/multifit.C`. It shows how to use several gaussian functions with different parameters on separate sub ranges of the same histogram.

To use a gaussian, or any other ROOT built in function, on a sub range you need to define a new `TF1`. Each is "derived" from the canned function `gaus`.

```c
// Create 4 TF1 objects, one for each subrange
g1 = new TF1("m1","gaus",85,95);
g2 = new TF1("m2","gaus",98,108);
g3 = new TF1("m3","gaus",110,121);
// The total is the sum of the three, each has three
// parameters.
total = new TF1("mstotal","gaus(0)+gaus(3)+gaus(6)",85,125);
```

Here we fill a histogram with bins defined in the array `x` (see `$ROOTSYS/tutorials/multifit.C`).

```c
// Create a histogram and set it's contents
h = new TH1F("g1", "Example of several fits in subranges", np, 85, 134);
h->SetMaximum(7);
for (int i=0;i<np;i++) {
  h->SetBinContent(i+1,x[i]);
}
// Define the parameter array for the total function
Double_t par[9];
```

When fitting simple functions, such as a gaussian, the initial values of the parameters are automatically computed by ROOT. In the more complicated case of the sum of 3 gaussian functions, the initial values of parameters must
be set. In this particular case, the initial values are taken from the result of the individual fits.

The use of the "+" sign is explained below.

```
// fit each function and add it to the list of functions
h->Fit(g1,"R");
h->Fit(g2,"R+");
h->Fit(g3,"R+");
```

```
// Get the parameters from the fit
g1->GetParameters(&par[0]);
g2->GetParameters(&par[3]);
g3->GetParameters(&par[6]);
```

```
// Use the parameters on the sum
total->SetParameters(par);
```

Adding Functions to The List

The example $ROOTSYS/tutorials/multifit.C also illustrates how to fit several functions on the same histogram. By default a Fit command deletes the previously fitted function in the histogram object. You can specify the option "*" in the second parameter to add the newly fitted function to the existing list of functions for the histogram.

```
root[] hist->Fit("f1","*","-2,2")
```

Note that the fitted function(s) are saved with the histogram when it is written to a ROOT file.

Combining Functions

You can combine functions to fit a histogram with their sum. Here is an example, the code is in $ROOTSYS/tutorials/FitDemo.C. We have a function that is the combination of a background and lorentzian peak. Each function contributes 3 parameters.

\[
y(E) = a_1 + a_2E + a_3E^2 + Ap \left( \frac{G/2}{(E-m)^2 + (G/2)^2} \right)
\]

```
// Quadratic background function
Double_t background(Double_t *x, Double_t *par) {
  return par[0] + par[1]*x[0] + par[2]*x[0]*x[0];
}
```

```
// Lorentzian Peak function
Double_t lorentzianPeak(Double_t *x, Double_t *par) {
  return 0.5*par[0]*par[1]/TMath::Pi() /
       TMath::Max( 1.e-10,
                    (x[0]-par[2])*(x[0]-par[2]) + .25*par[1]*par[1]);
}
```

```
// Sum of background and peak function
Double_t fitFunction(Double_t *x, Double_t *par) {
  return background(x,par) + lorentzianPeak(x,&par[3]);
}
```

This script creates a histogram and fits the combination of the two functions. First we define the two functions and the combination function:

```
// Quadatic background function
Double_t background(Double_t *x, Double_t *par) {
  return par[0] + par[1]*x[0] + par[2]*x[0]*x[0];
}
```

```
// Lorentzian Peak function
Double_t lorentzianPeak(Double_t *x, Double_t *par) {
  return 0.5*par[0]*par[1]/TMath::Pi() /
       TMath::Max( 1.e-10,
                    (x[0]-par[2])*(x[0]-par[2]) + .25*par[1]*par[1]);
}
```

```
// Sum of background and peak function
Double_t fitFunction(Double_t *x, Double_t *par) {
  return background(x,par) + lorentzianPeak(x,&par[3]);
}
```

```
void FittingDemo() {
  const int nBins = 60;
  Stat_t data[nBins] = { 6, 1,10,12, 6,13,23,22,15,21,
                         23,26,36,25,48,45,26,36,35,40,44,66,81,
                         75,57,48,45,46,41,35,36,53,26,39,32,
                         40,37,38,11,32,36,44,42,37,32,32,
  TH1F *histo = new TH1F("example_9_1", "Lorentzian Peak on Quadratic Background",60,0,3);
  for(int i=0; i < nBins; i++) {
    histo->SetBinContent(i+1,data[i]);
    histo->SetBinError(i+1,TMath::Sqrt(data[i]));
  }
  TF1 *fitFcn = new TF1("fitFcn",fitFunction,0,3,6);
  fitFcn->SetParameter(4,0.2); // width
  fitFcn->SetParameter(5,1);   // peak
  histo->Fit("fitFcn","V+");
```

This results in an ok fit for the polynomial function however the non-linear part (lorentzian) does not respond well.

```
// second try: set start values for some parameters
fitFcn->SetParameter(4,0.2); // width
fitFcn->SetParameter(5,1);   // peak
histo->Fit("fitFcn","V+");
```

This results in an ok fit for the polynomial function however the non-linear part (lorentzian) does not respond well.
// improve the picture:
TF1 *backFcn = new TF1("backFcn",background,0,3,3);
backFcn->SetLineColor(3);
TF1 *signalFcn = new TF1("signalFcn",lorentzianPeak,0,3,3);
signalFcn->SetLineColor(4);
Double_t par[6];
// writes the fit results into the par array
fitFcn->GetParameters(par);
backFcn->SetParameters(par);
backFcn->Draw("same");
signalFcn->SetParameters(&par[3]);
signalFcn->Draw("same");

This is the result:

For another example see:

Associated Function

One or more objects (typically a TF1*) can be added to the list of functions (fFunctions) associated to each histogram. A call to TH1::Fit adds the fitted function to this list. Given a histogram h, one can retrieve the associated function with:

TF1 *myfunc = h->GetFunction("myfunc");
6 A Little C++

This chapter introduces you to some useful insights into C++, to allow you to use of the most advanced features in ROOT. It is in no case a full course in C++.

**Classes, Methods and Constructors**

C++ extends C with the notion of class. If you’re used to structures in C, a class is a struct, that is a group of related variables, which is extended with functions and routines specific to this structure (class). What is the interest? Consider a struct that is defined this way:

```c
struct Line {
  float x1;
  float y1;
  float x2;
  float y2;
}
```

This structure represents a line to be drawn in a graphical window. \((x_1,y_1)\) are the coordinates of the first point, \((x_2,y_2)\) the coordinates of the second point.

In standard C, if you want to effectively draw such a line, you first have to define a structure and initialize the points (you can try this):

```c
Line firstline;
firstline.x1 = 0.2;
firstline.y1 = 0.2;
firstline.x2 = 0.8;
firstline.y2 = 0.9;
```

This defines a line going from the point \((0.2,0.2)\) to the point \((0.8,0.9)\). To draw this line, you will have to write a function, say `LineDraw(Line l)` and call it with your object as argument:

```c
LineDraw(firstline);
```

In C++, we would not do that. We would instead define a class like this:

```c
class TLine {
  Double_t x1;
  Double_t y1;
  Double_t x2;
  Double_t y2;
  TLine(int x1, int y1, int x2, int y2);
  void Draw();
}
```

Here we added two functions, that we will call methods or member functions, to the `TLine` class. The first method is used for initializing the line objects we would build. It is called a constructor.

The second one is the `Draw` method itself. Therefore, to build and draw a line, we have to do:

```c
TLine l(0.2,0.2,0.8,0.9);
l.Draw();
```

The first line builds the object `l` by calling its constructor. The second line calls the `TLine::Draw()` method of this object. You don't need to pass any parameters to this method since it applies to the object `l`, which knows the coordinates of the line. These are internal variables `x1, y1, x2, y2` that were initialized by the constructor.

**Inheritance and Data Encapsulation**

**Inheritance**

We've defined a `TLine` class that contains everything necessary to draw a line. If we want to draw an arrow, is it so different from drawing a line? We just have to draw a triangle at one end. It would be very inefficient to define the class `TArrow` from scratch. Fortunately, inheritance allows a class to be defined from an existing class. We would write something like:

```c
class TArrow : public TLine {
  int ArrowHeadSize;
  void Draw();
  void SetArrowSize(int arrowsize);
}
```

The keyword "public" will be explained later. The class `TArrow` now contains everything that the class `TLine` does, and a couple of things more, the size of the arrowhead and a function that can change it. The `Draw` method of `TArrow` will draw the head and call the draw method of `TLine`. We just have to write the code for drawing the head!

**Method Overriding**

Giving the same name to a method (remember: method = member function of a class) in the child class (TArrow) as in the parent (TLine) doesn't give any
This is called **overriding** a method. Draw in `TArrow` overrides Draw in `TLine`. There is no possible ambiguity since, when one calls the `Draw()` method, this applies to an object which type is known. Suppose we have an object `l` of type `TLine` and an object `a` of type `TArrow`. When you want to draw the line, you do:

```c++
l.Draw()
a.Draw()
```

Draw() from `TLine` is called. If you do:

```c++
Draw()
```

Draw() from `TArrow` is called and the arrow `a` is drawn.

**Data Encapsulation**

We have seen previously the keyword "public". This keyword means that every name declared public is seen by the outside world. This is opposed to "private" which means only the class where the name was declared private could see this name. For example, suppose we declare in `TArrow` the variable `ArrowHeadSize` private:

```c++
private:
  int ArrowHeadSize;
```

Then, only the methods (and member functions) of `TArrow` will be able to access this variable. Nobody else will see it. Even the classes that we could derive from `TArrow` will not see it. On the other hand, if we declare the method `Draw()` as public, everybody will be able to see it and use it. You see that the character public or private doesn’t depend of the type of argument. It can be a data member, a member function, or even a class.

For example, in the case of `TArrow`, the base class `TLine` is declared as public:

```c++
public:
  void Draw();
  void SetArrowSize(int arrowsize);
```

This means that all methods of `TArrow` will be able to access all methods of `TLine`, but this will be also true for anybody in the outside world. Of course, this is true provided that `TLine` accepts the outside world to see its methods/data members. If something is declared private in `TLine`, nobody will see it, even `TArrow` members, even if `TLine` is declared as a public base class.

What if `TLine` is declared "private" instead of "public"? Well, it will behave as any other name declared private in `TArrow`: only the data members and methods of `TArrow` will be able to access `TLine`, #5’s methods and data members, nobody else.

This may seem a little bit confusing and readers should read a good C++ book if they want more details. Especially since, besides public and private, a member can be protected.

Usually, one puts private the methods that the class uses internally, like some utilities classes, and that the programmer doesn’t want to be seen in the outside world.

With "good" C++ practice (which we have tried to use in ROOT), all data members of a class are private. This is called data encapsulation and is one of the strongest advantages of Object Oriented Programming (OOP). Private data members of a class are not visible, except to the class itself. So, if somebody in the outside world, if one wants to access those data members, one should use so called "getters" and "setters" methods, which are special methods used only to get or set the data members. The advantage is that if the programmers want to modify the inner workings of their classes, they can do so without changing what the user sees. The user doesn’t even have to know that something has changed (for the better, hopefully).

For example, in our `TArrow` class, we would have set the data member `ArrowHeadSize` private. The setter method is `SetArrowSize()`, we don’t need a getter method:

```c++
class TArrow : public TLine {
  private:
    int ArrowHeadSize;
  public:
    void Draw();
    void SetArrowSize(int arrowsize);
};
```

To define an arrow object you call the constructor. This will also call the constructor of `TLine`, which is the parent class of `TArrow`, automatically.

Then we can call any of the line or arrow public methods such as `SetArrowSize` and `Draw`.

```c++
root[] TArrow* myarrow = new TArrow(1,5,89,124);
root[] myarrow->SetArrowSize(10);
root[] myarrow->Draw();
```

## Creating Objects on the Stack and Heap

To explain how objects are created on the stack and on the heap we will use the `Quad` class. You can find the definition in `$ROOTSYS/tutorials/Quad.h` and `Quad.cxx`.

The `Quad` class has four methods. The constructor and destructor, `Evaluate` which evaluates \( ax^2 + bx + c \), and `Solve` which solves the quadratic equation \( ax^2 + bx + c = 0 \).

```c++
class Quad {
  public:
    Quad(Float_t a, Float_t b, Float_t c);
    ~Quad();
    Float_t Evaluate(Float_t x) const;
    void Solve() const;
  private:
    Float_t fA;
    Float_t fB;
    Float_t fC;
};
```

To define a quad object you call the constructor. The destructor will call the destructor of `TArrow`, which is the parent class of `TArrow`, automatically.
Quad.cxx:

```cpp
#include <iostream.h>
#include <math.h>
#include "Quad.h"

Quad::Quad(Float_t a, Float_t b, Float_t c) {
    fA = a;
    fB = b;
    fC = c;
}

Quad::~Quad() {
    cout << "deleting object with coeffts: " << fA <<"," << fB <<"," << fC << endl;
}

Float_t Quad::Evaluate(Float_t x) const {
    return fA*x*x + fB*x + fC;
}

void Quad::Solve() const {
    Float_t temp = fB*fB - 4.*fA*fC;
    if ( temp > 0. ) {
        temp = sqrt( temp );
        cout << "There are two roots: " << (-fB - temp ) / (2.*fA) << " and ";
        << (-fB + temp ) / (2.*fA) << endl;
    } else {
        if ( temp == 0. ) {
            cout << "There are two equal roots: " << -fB / (2.*fA) << endl;
        } else {
            cout << "There are no roots" << endl;
        }
    }
}
```

Let's first look how we create an object. When we create an object by

```cpp
root[] Quad my_object(1.,2.,-3.);
```

We are creating an object on the stack. A FORTRAN programmer may be familiar with the idea; it's not unlike a local variable in a function or subroutine. Although there are still a few old timers who don't know it, FORTRAN is under no obligation to save local variables once the function or subroutine returns unless the SAVE statement is used. If not then it is likely that FORTRAN will place them on the stack and they will "pop off" when the RETURN statement is reached.

To give an object more permanence it has to be placed on the heap.

```cpp
root[] Quad* my_objptr = new Quad(1., 2., -3.);
```

The second line declares a pointer to Quad called my_objptr. From the syntax point of view, this is just like all the other declarations we have seen so far, i.e. this is a stack variable. The value of the pointer is set equal to new Quad(1., 2., -3.);

new, despite its looks, is an operator and creates an object or variable of the type that comes next. Quad in this case, on the heap. Just as with stack objects it has to be initialized by calling its constructor. The syntax requires that the argument list follow the type. This one statement has brought two items into existence, one on the heap and one on the stack. The heap object will live until the delete operator is applied to it.

There is no FORTRAN parallel to a heap object; variables either come and go as control passes in and out of a function or subroutine, or, like a COMMON block variables, live for the lifetime of the program. However, most people in HEP who use FORTRAN will have experience of a memory manager and the act of creating a bank is a good equivalent of a heap object. For those who know systems like ZEBRA, it will come as a relief to learn that objects don't move, C++ does not garble collect, so there is never a danger that a pointer to an object becomes invalid for that reason. However, having created an object, it is the user's responsibility to ensure that it is deleted when no longer needed, or to pass that responsibility onto to some other object. Failing to do that will result in a memory leak, one of the most common and most hard-to-find C++ bugs.

To send a message to an object via a pointer to it, you need to use the "->" operator e.g.:
class and create a heap object:

```
root[] .L Quad.cxx
root[] Quad* my_objptr = new Quad(1., 2., -3.);
```

To delete the object:

```
root[] delete my_objptr;
root[] my_objptr = 0;
```

You should see the print out from its destructor. Setting the pointer to zero afterwards isn't strictly necessary (and CINT does it automatically), but the object is no more, and any attempt to use the pointer again will, as has already been stated, cause grief.

So much for heap objects, but how do stack objects get deleted? In C++ a stack object is deleted as soon as control leaves the innermost compound statement that encloses it. So it is singularly futile to do something like:

```
root[] { Quad my_object(1., 2., -3.); }
```

CINT does not follow this rule; if you type in the above line you will not see the destructor message. As explained in the Script lesson, you can load in compound statements, which would be a bit pointless if everything disappeared as soon as it was loaded! Instead, to reset the stack you have to type:

```
root[] gROOT->Reset();
```

This sends the Reset message via the global pointer to the ROOT object, which, amongst its many roles, acts as a resource manager. Start ROOT again and type in the following:

```
root[] .L Quad.cxx
root[] Quad my_object(1., 2., -3.);
root[] Quad* my_objptr = new Quad(4., 5., -6.);
root[] gROOT->Reset();
```

You will see that this deletes the first object but not the second. We have also painted ourselves into a corner, as `my_objptr` was also on the stack. This command will fail.

```
root[] my_objptr->Solve();
```

CINT no longer knows what `my_objptr` is. This is a great example of a memory leak; the heap object exists but we have lost our way to access it. In general, this is not a problem. If any object will outlive the compound statement in which it was created then it will be pointed to by a more permanent pointer, which frequently is part of another heap object. See Resetting the Interpreter Environment in the chapter CINT the C++ Interpreter.
The subject of this chapter is CINT, ROOT's command line interpreter and script processor. First, we explain what CINT is and why ROOT uses it. Then CINT as the command line interpreter, the CINT commands, and CINT's extensions to C++ are discussed. CINT as the script interpreter is also explained and illustrated with several examples.

What is CINT?

CINT, which is pronounced C-int, is a C++ interpreter. An interpreter takes a program, in this case a C++ program, and carries it out by examining each instruction and in turn executing the equivalent sequence of machine language. For example, an interpreter translates and executes each statement in the body of a loop "n" times. It does not generate a machine language program. This may not be a good example, because most interpreters have become 'smart' about loop processing.

A compiler on the other hand, takes a program and makes a machine language executable. Once compiled the execution is very fast, which makes a compiler best suited for the case of "built once, run many times". For example, the ROOT executable is compiled occasionally and runs for the first time (depending on the CPU). Once compiled it runs very fast. On the average, a compiled program runs ten times faster than an interpreted one.

Because it takes much time to compile, using a compiler is cumbersome for rapid prototyping when one changes and rebuilds as often as every few minutes. An interpreter, optimized for code that changes often and runs a few times, is the perfect tool for this.

Most of the time, an interpreter has a separate scripting language, such as Python, IDL, and PERL, designed especially for interpretation, rather than compilation. However, the advantage of having one language for both is that once the prototype is debugged and refined, it can be compiled without translating the code to a compiled language.

CINT being a C++ interpreter is the tool for rapid prototyping and scripting in C++. It is a stand-alone product developed by Masaharu Goto. It's executable comes with the standard distribution of ROOT ($ROOTSYS/bin/cint), and it can also be installed separately from:

http://root.cern.ch/CINT.html

This page also has links to all the CINT documentation. The downloadable tar file contains documentation, the CINT executable, and many demo scripts, which are not included in the regular ROOT distribution.

Here is a list of CINT's main features:

- Supports K&R-C, ANSI-C, and ANSI-C++
  CINT covers 80-90% of the K&R-C, ANSI-C and C++ language constructs. It supports multiple inheritance, virtual function, function overloading, operator overloading, default parameter, template, and much more. CINT is robust enough to interpret its own source code. CINT is not designed to be a 100% ANSI/ISO compliant C++ language processor. It is a portable scripting language environment, which is close enough to the standard C++.

- Interprets Large C/C++ source code
  CINT can handle huge C/C++ source code, and loads source files quickly. It can interpret its own, over 70,000 lines source code.

- Enables mixing Interpretation & Native Code
  Depending on the need for execution speed or the need for interaction, one can mix native code execution and interpretation. "makeCINT" encapsulates arbitrary C/C++ objects as a precompiled libraries. A precompiled library can be configured as a dynamically linked library. Accessing interpreted code and precompiled code can be done seamlessly in both directions.

- Provides a Single-Language solution
  CINT/makeCINT is a single-language environment. It works with any ANSI-C/C++ compiler to provide the interpreter environment on top of it.

- Simplifies C++
  CINT is meant to bring C++ to the non-software professional. C++ is simpler to use in the interpreter environment. It helps the non-software professional (the domain expert) to talk the same language as the software counterpart.

- Provides RTTI and a Command Line
  CINT can process C++ statements from command line, dynamically define/erase class definition and functions, load/unload source files and libraries. Extended Run Time Type Identification is provided, allowing you to explore unthinkable way of using C++.

- Has a Built-in Debugger and Class Browser
  CINT has a built-in debugger to debug complex C++ code. A text based class browser is part of the debugger.

- Is Portable
  CINT works on number of operating systems: UNIX, Linux, Solaris, AIX, Alpha-OSF, IRIX, FreeBSD, NetBSD, NEC EWS4800, VMS, Windows-NT, Windows-9x, MacOS, VMS, NextStep, Convex.
The ROOT Command Line Interface

Start up a ROOT session by typing ROOT at the system prompt.

```c
hproot) [199] root
*******************************************
*                                         *
*        W E L C O M E  to  R O O T       *
*                                         *
*   Version   2.25/02      21 August 2000 *
*                                         *
*  You are welcome to visit our Web site  *
*          http://root.cern.ch            *
*                                         *
*******************************************
Type ? for help. Commands must be C++ statements. Enclose multiple statements between { }.

Now create a TLine object:

```c
root [] TLine l
root [] l.Print()
TLine X1=0.000000 Y1=0.000000 X2=0.000000 Y2=0.000000
root [] l.SetX1(10)
root [] l.SetY1(11)
root [] l.Print()
TLine X1=10.000000 Y1=11.000000 X2=0.000000 Y2=0.000000
root [] .g
... 0x4038f080 class TLine l , size=40
... 0x0403f080 class TLine l , size=40
0x0 protected: Double_t fx1 //X of 1st point
0x0 protected: Double_t fy1 //Y of 1st point
0x0 protected: Double_t fx2 //X of 2nd point
0x0 protected: Double_t fy2 //Y of 2nd point
0x0 private: static class TClass* fgIsA
```

Here we note:

• Terminating ; not required (see the section ROOT/CINT Extensions to C++).
• Emacs style command line editing.
• Raw interpreter commands start with a . (dot).

Here we see:

• Use .class as quick help and reference
• Unix like I/O redirection (; is required before >)
• Use ? to get help on all "raw" interpreter commands
Now let's execute a multi-line command:

```
root \{
end with '}
TLine l;
end with '}
for (int i = 0; i < 5; i++) {
end with '}
l.SetX1(i);
end with '}
l.SetY1(i+1);
end with '}
l.Print();
end with '}
```

Here we note:
- A multi-line command starts with a `{` and ends with a `}`.
- Every line has to be correctly terminated with a `;` (like in "real" C++).
- All objects are created in global scope.
- There is no way to back up, you are better off writing a script.
- Use `.q` to exit root.

The ROOT Script Processor

ROOT script files contain pure C++ code. They can contain a simple sequence of statements like in the multi command line example given above, but also arbitrarily complex class and function definitions.

Un-named Scripts

Let's start with a script containing a simple list of statements (like the multi-command line example given in the previous section). This type of script must start with a `{` and end with a `}` and is called an un-named script. Assume the file is called `script1.C`.

```
#include <iostream.h>
cout << " Hello" << endl;
float x = 3.;
float y = 5.;
int   i = 101;
cout << " x = "<<x<<" y = "<<y<<" i = "<>i<<endl;
return 0;
```

To execute the stream of statements in `script1.C` do:

```
root [] .x script1.C
```

This loads the contents of file `script1.C` and executes all statements in the interpreter's global scope.

One can re-execute the statements by re-issuing ".x script1.C" (since there is no function entry point).

Scripts are searched for in the Root.MacroPath as defined in your .rootrc file. To check which script is being executed use:

```
root [] .which script1.C
/home/rdm/root/./script1.C
```

Named Scripts

Let's change the un-named script to a named script. Copy file `script1.C` to `script2.C` and add a function statement. Like this:

```
#include <iostream.h>
int main()
{
   cout << " Hello" << endl;
   float x = 3.;
   float y = 5.;
   int   i = 101;
   cout << " x = "<<x<<" y = "<<y<<" i = "<>i<<endl;
   return 0;
}
```

Notice that no surrounding `{` are required in this case. To execute function `main()` in `script2.C` do:

```
root [] .L script2.C // load script in memory
root [] main() // execute entry point main
Hello
x = 3 y = 5 i = 101
(int)0
root [] main() // execute main() again
Hello
x = 3 y = 5 i = 101
(int)0
root [] .func // list all functions known by CINT
filename line:size busy function type and name
...  script2.C 4:9 0 public: int main();
```

The last command shows that `main()` has been loaded from file `script2.C`, that the function `main()` starts on line 4 and is 9 lines long. Notice that once a function has been loaded it becomes part of the system just like a compiled function.
Now we copy file script2.C to script3.C and change the function name from `main()` to `script3(int j = 10):

```c
#include <iostream.h>
int script3(int j = 10) {
  cout << 'Hello' << endl;
  float x = 3.;
  float y = 5.;
  int i = j;
  cout << 'x = ' << x << ' y = ' << y << ' i = ' << i << endl;
  return 0;
}
```

To execute `script3()` in `script3.C` type:

```
root [] .x script3.C(8)
```

This loads the contents of file `script3.C` and executes entry point `script3(8)`. Note that the above only works when the filename (minus extension) and function entry point are both the same. Function `script3()` can still be executed multiple times:

```
root [] script3()
Hello
x = 3 y = 5 i = 10 (int)0
root [] script3(33)
Hello
x = 3 y = 5 i = 33 (int)0
```

In a named script, the objects created on the stack are deleted when the function exits. For example, this scenario is very common. You create a histogram in a named script on the stack. You draw the histogram, but when the function exits the canvas is empty and the histogram disappeared.

To avoid histogram from disappearing you can create it on the heap (by using `new`). This will leave the histogram object intact, but the pointer in the named script scope will be deleted.

Since histograms (and trees) are added to the list of objects in the current directory, you can always retrieve them to delete them if needed.

```
root [] TH1F *h = (TH1F*)gDirectory->Get("myHist");
```

In addition, histograms and trees are automatically deleted when the current directory is closed. This will automatically take care of the clean up. See chapter Input/Output.

### Executing a Script from a Script

You may want to execute a script conditionally inside another script. To do that you need to call the interpreter and you can do that with `TROOT::ProcessLine()`.

Here is an example from $ROOTSYS/tutorials/cernstaff.C that calls a script to build the root file if it does not exist:

```c
void cernstaff () {
  if (gSystem->AccessPathName("cernstaff.root")) {
    gROOT->ProcessLine(".x cernbuild.C");
  }
}
```

**Resetting the Interpreter Environment**

Variables created on the command line and in un-named scripts are in the interpreter's global scope, which makes the variables created in un-named scripts available on the command line event after the script is done executing. This is the opposite of a named script where the stack variables are deleted when the function in which they are defined has finished execution.

When running an un-named script over again and this is frequently the case since un-named scripts are used to prototype, one should reset the global environment to clear the variables. This is done by calling `gROOT->Reset()`. It is good practice, and you will see this in the examples, to begin un-named script with `gROOT->Reset()`. It clears the global scope to the state just before executing the previous script (not including any logon scripts).

The `gROOT->Reset()` calls the destructor of the objects if the object was created on the stack. If the object was created on the heap (via `new`) it is not deleted, but the variable is no longer associated with it. Creating variables on the heap in un-named scripts and calling `gROOT->Reset()` without you calling the destructor explicitly will cause a memory leak.

This may be surprising, but it follows the scope rules. For example, creating an object on the heap in a function (in a named script) without explicitly deleting it will also cause a memory leak. Since when exiting the function only the stack variables are deleted.

The code below shows `gROOT->Reset` calling the destructor for the stack variable, but not for the heap variable. In the end, neither variable is available, but the memory for the heap variable is not released.

```c
root [] Debug = 1
(const int)1
root [] TFile *stackVar = new TFile("stack.root","RECREATE")
TKey Writing 86 bytes at address 64 for ID= stack.root Title=
root [] TFile *heapVar = new TFile("heap.root","RECREATE")
TKey Writing 84 bytes at address 64 for ID= heap.root Title=
```

We turn on `Debug` to see what the subsequent calls are doing. Then we create two variables, one on the stack and one on the heap.
When we call `gROOT->Reset()`, CINT tells us that the destructor is called for the stack variable, but it doesn’t mention the heap variable.

Neither variable is available in after the call to `reset()`.

The object on the stack is deleted and shows a null pointer when we do a `FindObject`. However, the heap object is still around and taking up memory.

---

**A Script Containing a Class Definition**

Let's create a small class `TMyClass` and a derived class `TChild`. The virtual `TMyClass::Print()` method is overridden in `TChild`. Save this in file called `script4.C`.

```cpp
#include <iostream.h>

class TMyClass {
   private:
      float fX; // x position in centimeters
      float fY; // y position in centimeters
   public:
      TMyClass() { fX = fY = -1; }
      virtual void Print() const;
      void SetX(float x) { fX = x; }
      void SetY(float y) { fY = y; }
   }

   void TMyClass::Print() const // parent print method
   {
      cout << "fX = " << fX <<", fY = " << fY << endl;
   }

   //-----------------------------
   class TChild : public TMyClass {
      public:
         void Print() const;
   }

   void TChild::Print() const // child print method
   {
      cout << "This is TChild::Print()" << endl;
      TMyClass::Print();
   }
```
To execute script4.C do:

```
root [] .L script4.C
root [] TMyClass *a = new TChild
root [] a->Print()
```

```
This is TChild::Print()
fx = -1, fy = -1
root [] a->SetX(10)
root [] a->SetY(12)
root [] a->Print()
```

```
This is TChild::Print()
fx = 10, fy = 12
root [] .class TMyClass
```

```
size=0x8 FILE:script4.C LINE:3
List of base class-----------------------------------
List of member variable-----------------------------
Defined in TMyClass
0x0  private: float fX
0x4  private: float fY
List of member function-----------------------------
Defined in TMyClass
```

```
filename  line:size busy function type and name
script4.C  16:5  0  public: class TMyClass
TMyClass(void);
script4.C  22:4  0  public: void Print(void);
script4.C  12:1  0  public: void SetX(float x);
script4.C  13:1  0  public: void SetY(float y);
root [] .q
```

As you can see an interpreted class behaves just like a compiled class.

There are some limitations for a class created in a script:

1. They cannot inherit from TObject. Currently the interpreter cannot patch the virtual table of compiled objects to reference interpreted objects.
2. Because the I/O is encapsulated in TObject and a class defined in a script cannot inherit from TObject, it can not be written to a ROOT file.

For ways to add a class with a shared library and with ACLIC, see the chapter: "Adding a Class"

### Debugging Scripts

A powerful feature of CINT is the ability to debug interpreted functions by means of setting breakpoints and being able to single step through the code and print variable values on the way. Assume we have script4.C still loaded, we can then do:

```
root [] .b TChild::Print
Break point set to line 26 script4.C
root [] a.Print()
```

```
26  TChild::Print() const
27  {
28      cout << "This is TChild::Print()" << endl;
FILE:script4.C LINE:28 cint>
311  operator<<(ostream& ostr, G__CINT_ENDL& i)
{return(endl(ostr));
FILE:iostream.h LINE:311 cint> .s
311  operator<<(ostream& ostr, G__CINT_ENDL& i)
{return(endl(ostr));
FILE:iostream.h LINE:311 cint> .s
This is TChild::Print()
29  MyClass::Print();
FILE:script4.C LINE:29 cint> .s
16  MyClass::Print() const
17  {
18      cout << "fx = " << fx << " fy = " << fy << endl;
{float):1.00000000000000e+01
FILE:script4.C LINE:18 cint> .s
311  operator<<(ostream& ostr, G__CINT_ENDL& i)
{return(endl(ostr));
FILE:iostream.h LINE:311 cint> .s
311  operator<<(ostream& ostr, G__CINT_ENDL& i)
{return(endl(ostr));
FILE:iostream.h LINE:311 cint> .s
fx = 10, fy = 12
19  }
30  }
2  }
root [] .q
```
Inspecting Objects

An object of a class inheriting from TObject can be inspected, with the Inspect method. The TObject::Inspect method creates a window listing the current values of the objects members. For example, this is a picture of TFile.

```
root[] TFile f("staff.root")
root[] f.Inspect()
```

You can see the pointers are in red and can be clicked on to follow the pointer to the object. For example, here we clicked on fKeys, the list of keys in memory.

```
root[] hpx.Draw()
NULL
Warning in <MakeDefCanvas>: creating a default canvas with name c1
```

The first command shows the first extension; the declaration of f may be omitted when "new" is used. CINT will correctly create f as pointer to object of class TFile.

The second extension is shown in the second command. Although f is a pointer to TFile we don't have to use the pointer de-referencing syntax "->" but can use the simple "." notation.

```
root[] f = new TFile("hsimple.root")
```

ROOT/CINT Extensions to C++

In the next example, we demonstrate three of the most important extensions ROOT/CINT makes to C++. Start ROOT in the directory $ROOTSYS/tutorials (make sure to have first run ".x hsimple.C"):

```
root[] f = new TFile("hsimple.root")
```

The first command shows the first extension; the declaration of f may be omitted when "new" is used. CINT will correctly create f as pointer to object of class TFile.
The third extension is more important. In case CINT cannot find an object being referred, it will ask ROOT to search for an object with an identical name in the search path defined by TROOT::FindObject(). If ROOT finds the object, it returns CINT a pointer to this object and a pointer to its class definition and CINT will execute the requested member function. This shortcut is quite natural for an interactive system and saves much typing. In this example, ROOT searches for hpx and finds it in <i>simple.root</i>.

The fourth is shown below. There is no need to put a semicolon at the end of a line. The difference between having it and leaving it off is that when you leave it off the return value of the command will be printed on the next line. For example:

```
root[] 23+5 // no semicolon prints the return value
[root] 28; // semicolon no return value is printed
```

Be aware that these extensions do not work when the interpreter is replaced by a compiler. Your code will not compile, hence when writing large scripts, it is best to stay away from these shortcuts. It will save you from having problems compiling your scripts using a real C++ compiler.

**ACLIc - The Automatic Compiler of Libraries for CINT**

Instead of having CINT interpret your script there is a way to have your scripts compiled, linked and dynamically loaded using the C++ compiler and linker. The advantage of this is that your scripts will run with the speed of compiled C++ and that you can use language constructs that are not fully supported by CINT. On the other hand, you cannot use any CINT shortcuts (see CINT extensions) and for small scripts, the overhead of the compile/link cycle might be larger than just executing the script in the interpreter.

ACLIc will build a CINT dictionary and a shared library from your C++ script, using the compiler and the compiler options that were used to compile the ROOT executable. You do not have to write a makefile remembering the correct compiler options, and you do not have to exit ROOT.

**Usage**

Before you can compile your interpreted script you need to add include statements for the classes used in the script. Once you did that, you can build and load a shared library containing your script. To load it, use the <i>.L</i> command and append the file name with a “++”.

```
root[] .L MyScript.C++
root[] .files
  -
  - *file="/home/./MyScript_C.so"
```

The + option generates the shared library and naming it by taking the name of the file "filename" but replacing the dot before the extension by an underscore and by adding the shared library extension for the current platform.

For example on most platforms, hsimple.cxx will generate hsimple_cxx.so.

**Intermediate Steps and Files**

ACLIc executes two steps and a third one if needed. These are:

- Calling <i>rootcint</i> to create a CINT dictionary, <i>rootcint</i> is a ROOT specific version of makecint, CINT’s generic dictionary generator.
- Calling the compiler to build the shared library from the script.
- Executing the shared library.

It uses the directive <i>fMakeSharedLibs</i> to create a shared library. If loading the shared library fails, it tries to output a list of missing symbols by creating an executable (on some platforms like OSF, this does not HAVE to be an executable) containing the script. It uses the directive <i>fMakeExe</i> to do so. For both directives, before passing them to <i>TSystem</i>::Exec, it expands the variables <i>$SourceFiles</i>, <i>$SharedLib</i>, <i>$LibName</i>, <i>$IncludePath</i>, <i>$LinkedLibs</i>, <i>$ExeName</i> and <i>$ObjectFiles</i>. See <i>SetMakeSharedLib()</i> for more information on those variables.

If we execute a .files command we can see the newly created shared library is in the list of loaded files. The + command will check for a more recent timestamp on the script and the script header file before rebuilding the shared library. Note that it does not automatically check the time stamp of the include files except for the one that has the same name as the script with the header extension.

To ensure that the shared library is rebuilt you can use the ++ syntax:

```
root[] .L MyScript.C++
```

To build, load, and execute the function with the same name as the file you can use the .x command. This is the same as executing a named script. You can have parameters and use .x or .X. The only difference is you need to append a + or a ++.

```
root[] .x MyScript.C+ (4000)
Creating shared library /home/./MyScript_C.so
```

The alternative to <i>.L</i> is to use <i>gROOT::LoadMacro</i>. For example, in one script you can use ACLIc to compile and load another script.

```
gROOT->LoadMacro("MyScript.C++")
gROOT->LoadMacro("MyScript.C++")
```

* and ++ have the same meaning as described above. You can also use the <i>gROOT::Macro</i> method to load and execute the script.

```
gROOT->Macro("MyScript_C++")
```

**NOTE:** You should not call ACLIc with a script that has a function called main(). When ACLIc calls rootcint with a function called main it tries to add every symbol it finds while parsing the script and the header files to the dictionary. This includes the system header files and the ROOT header files. This will result in duplicate entries at best and crashes at worst, because some classes in ROOT needs special attention before they can be added to the dictionary.

# Calling the compiler to build the shared library from the script

The + option generates the shared library and naming it by taking the name of the file "filename" but replacing the dot before the extension by an underscore and by adding the shared library extension for the current platform.

For example on most platforms, hsimple.cxx will generate hsimple_cxx.so.
These types of headers can be included in interpreted and compiled mode:

In a script you can set the include path:

```
#include "-I$HOME/mypackage/include 
```

rootcint will be available at the command line even if ACLiC is used. CINT and rootcint will not be included in the dictionary, and consequently, \texttt{gArray} will not be available at the command line even if ACLiC is used. CINT and rootcint will ignore all statements between the \\
```
#ifdef (__CINT__) || defined (__MAKECINT__) 
```
and \\
```
#endif 
```
. If you want to use \texttt{gArray} in the same script as its declaration, you can raise the ROOT debug level (gDebug = 5).

### Moving between Interpreter and Compiler

The best way to develop portable scripts is to make sure you can always run them with both, the interpreter and with ACLiC. To do so, do not use the CINT extensions and program around the CINT limitations. When it is not possible or desirable to program around the CINT limitations, you can use the C preprocessor symbols defined for CINT and rootcint.

The preprocessor symbol \_\_CINT\_\_ is defined for both CINT and rootcint. The symbol \_\_MAKECINT\_\_ is only defined in rootcint.

Use \#define\n```
#ifdef (__CINT__) || defined (__MAKECINT__) 
```
!\#define\n```
#endif 
```
to bracket code that needs to be seen by the compiler and rootcint, but will be invisible to the interpreter.

Use \#define\n```
#ifdef (__CINT__) 
```
to bracket code that should be seen only by the compiler and not by CINT or rootcint.

For example, the following will hide the declaration and initialization of the array \texttt{gArray} from both CINT and rootcint.

```
#if defined(__CINT__) 
int gArray[]} = \{2, 3, 4};
#endif
```

Because ACLiC calls rootcint to build a dictionary, the declaration of \texttt{gArray} will not be included in the dictionary, and consequently, \texttt{gArray} will not be available at the command line even if ACLiC is used. CINT and rootcint will ignore all statements between the \\
```
#ifdef (__CINT__) 
```
and \\
```
#endif 
```
. If you want to use \texttt{gArray} in the same script as its declaration, you can do so. However, if you want use the script in the interpreter you have to bracket the usage of \texttt{gArray} between \#if's, since the definition is not visible.

If you add the following preprocessor statements, \texttt{gArray} will be visible to rootcint but still not visible to CINT. If you use ACLiC, \texttt{gArray} will be available at the command line and be initialized properly by the compiled code.

```
#if defined(__CINT__) 
int gArray[]} = \{2, 3, 4}; 
#elif defined (__MAKECINT__) 
int gArray[]; 
#endif
```

We recommend you always write scripts with the needed include statements. In most cases, the script will still run with the interpreter. However, a few header files are not handled very well by CINT.

These types of headers can be included in interpreted and compiled mode:

- The subset of standard C/C++ headers defined in $ROOTSYS/cint/include.
- Headers of classes defined in a previously loaded library (including ROOT's own). The defined class must have a name known to ROOT (i.e. a class with a ClassDef).

A few headers will cause problems when they are included in interpreter mode, because they are already included by the interpreter itself. In general, the interpreter needs to know whether to use the interpreted or compiled version. The mode of the definition needs to match the mode of the reference.

Here are the cases that need to be excluded in interpreted mode, but included for rootcint. Bracket these with:

```
#ifdef (__CINT__) || defined (__MAKECINT__) 
```

- All CINT headers, see $ROOTSYS/cint/inc
- Headers with classes named other than the file name. For example: \texttt{Rtypes.h} and \texttt{SuitTypes.h}.
- Headers with a class defined in a libraries before the library is loaded. For example: having a \#include \"TlorenzVector.h\" before \$System-\>Load("libPhysics\")

This will also cause problems when compiling the script, but a clear error message will be given. With the interpreter it may core dump. Bracket these type of include statements with \#if \#define \_\_CINT\_\_\_, this will print an error in both modes.

Hiding header files from rootcint that are necessary for the compiler but optional for the interpreter can lead to a subtle but fatal errors. For example:

```
#ifdef __CINT__ 
#include "TTree.h"
#else 
class TTree; 
#endif
```

```
class subTree : public TTree { 

```
In this case, rootcint does not have enough information about the \texttt{TTree} class to produce the correct dictionary file. If you try this, rootcint and compiling will be error free, however, instantiating a \texttt{subTree} object from the CINT command line will cause a fatal error.

In general it is recommended to let rootcint see as many header files as possible.

### Setting the Include Path

You can get the include path by typing:

```
root [] .include
```

You can append to the include path by typing:

```
root [] .include "-I$HOME/mypackage/include "
```

In a script you can set the include path:
gSystem->SetIncludePath("-I$HOME/mypackage/include")

The $ROOTSYS/include directory is automatically appended to the include path, so you don't have to worry about including it, however if you have already added a path, this command will overwrite it.
8 Object Ownership

An object has ownership of another object if it has permission to delete it. Usually ownership is held by a collection or a parent object such as a pad.

To prevent memory leaks and multiple attempts to delete an object, you need to know which objects are owned by ROOT and which are owned by you.

The following rules apply to the ROOT classes.

- Histograms, trees, and event lists created by the user are owned by current directory (gDirectory). When the current directory is closed or deleted the objects it owns are deleted also.
- The TROOT master object (gROOT) has several collections of objects. Objects that are members of these collections are owned by gROOT (see the paragraph “Ownership by the Master TROOT Object (gROOT)” below).
- Objects created by another object, for example the function object (e.g. TF1) created by the TH1::Fit method is owned by the histogram.
- An object created by DrawCopy methods, is owned by the pad it is drawn in.

If an object fits none of these cases, the user has ownership. The next paragraphs describe each rule and user ownership in more detail.

Ownership by Current Directory (gDirectory)

When a histogram, tree, or event list (TEventList) is created, it is added to the list of objects in the current directory by default. You can get the list of objects in a directory and retrieve a pointer to a specific object with the GetList method. This example retrieves a histogram.

```c
TH1 *h = (TH1*)gDirectory->GetList()->FindObject("myHist");
```

The method `gDirectory::GetList()` returns a TList of objects in the directory. It looks in memory, and is implemented in all ROOT collections.

You can change the directory of a histogram, tree, or event list with the SetDirectory method. Here we use a histogram for an example, but the same applies to trees and event lists.

```c
h->SetDirectory(newDir)
```

You can also remove a histogram from a directory by using `SetDirectory(0)`. Once a histogram is removed from the directory, it will not be deleted when the directory is closed. It is now your responsibility to delete this histogram once you have finished with it.

To change the default that automatically adds the histogram to the current directory, you can call the static function:

```c
TH1::AddDirectory(kFALSE);
```

All histograms created here after will not be added to the current directory. In this case, you own all histogram objects and you will need to delete them and clean up the references.

You can still set the directory of a histogram by calling `SetDirectory` once it has been created as described above.

Note that, when a file goes out of scope or is closed all objects on its object list are deleted.

Ownership by the Master TROOT Object (gROOT)

The master object gROOT, maintains several collections of objects. For example, a canvas is added to the collection of canvases and it is owned by the canvas collection.

These collections are also displayed in the root folder of the Object Browser.

Most of these collections are self explanatory. The special cases are the collections of specials and cleanups.

The Collection of Specials

This collection contains objects of the following classes: TCut, TMultidimFit, TPrincipal, TChains. In addition it contains the gHtml object, gMinuit objects, and...
the array of contours graphs (TGraph) created when calling the Draw method of a histogram with the "CONT, LIST" option.

Access to the Collection Contents
The current content for the collection listed above can be accessed with the corresponding gROOT->GetListOf method (for example gROOT->GetListOfCanvases). In addition, gROOT->GetListOfBrowsables returns a collection of all objects visible on the left side panel in the browser (see the image of the Object Browser above).

Ownership by Other Objects
When an object is created by another, the creating object is the owner of the one it created. For example:

myHisto->Fit("gaus")

The call to Fit copies the global TF1 object gaus and attaches the copy to the histogram. When the histogram is deleted, the copy of gaus is deleted also.

When a pad is deleted or cleared, all objects in the pad with the kCanDelete bit set are automatically deleted. Currently the objects created by the DrawCopy methods, have the kCanDelete bit set and are therefore owned by the pad.

Ownership by the User
The user owns all objects not described in one of the above cases.

TObject has two bits, kCanDelete and kMustCleanup, that influence how an object is managed (in TObject::fBits). These are in an enumeration in TObject.h. To set these bits do:

myObject->SetBit(kCanDelete)
myObject->SetBit(kMustCleanup)

The bits can be reset and tested with the TObject::ResetBit and TObject::TestBit methods.

The kCanDelete Bit
The gROOT collections (see above) own their members and will delete them regardless of the kCanDelete bit. In all other collections, when the collection Clear method is called (i.e. TList::Clear()), members with the kCanDelete bit set, are deleted and removed from the collection. If the kCanDelete bit is not set, the object is only removed from the collection but not deleted.

If a collection Delete(TList::Delete()) method is called, all objects in the collection are deleted without considering the kCanDelete bit.

It is important to realize that deleting the collection (i.e. delete MyCollection), DOES NOT delete the members of the collection. If the user specified MyCollection->SetOwner() the collection owns the objects and delete MyCollection will delete all its members. Otherwise you need to:

// delete all member objects in the collection
MyCollection->Delete();
// and delete the collection object
delete MyCollection;

Note that kCanDelete is automatically set by the DrawCopy method and it can be set for any object by the user.

For example, all graphics primitives must be managed by the user. If you want TCanvas to delete the primitive you created you have set the kCanDelete bit.

The kCanDelete bit setting is displayed with TObject::ls(). The last number is either 1 or 0 and is the kCanDelete bit.

The kMustCleanup Bit
When the kMustCleanup bit is set, the object destructor will remove the object and its references from all collections in the clean up collection (gROOT::fCleanups).

An object can be in several collections, for example if an object is in a browser and on two canvases. If the kMustCleanup bit is set, it will automatically be removed from the browser and both canvases when the destructor of the object is called.

kMustCleanup is set
• When an object is added to a pad (or canvas) in TObject::AppendPad.
• When an object is added to a TBrowser with TBrowser::Add.
• When an object is added to a TFolder with TFolder::Add.
• When creating an inspector canvas with TInspectorCanvas::Inspector.
• When creating a TCanvas.
• When painting a frame for a pad, the frame’s kMustClean up is set in TPad::PaintPadFrame

The user can add his own collection to the collection of clean ups, to take advantage of the automatic garbage collection.
For example:

```cpp
// create two list
TList *myList1, *myList2;
// add both to of clean ups
gROOT->GetListOfCleanUps()->Add(myList1);
gROOT->GetListOfCleanUps()->Add(myList2);
// assuming myObject is in myList1 and myList2, when calling:
delete myObject;
// the object is deleted from both lists
```
9 Graphics and the Graphical User Interface

Graphical capabilities of ROOT range from 2D objects (lines, polygons, arrows) to various plots, histograms, and 3D graphical objects. In this chapter, we are going to focus on principals of graphics and 2D objects. Plots and histograms are discussed in a chapter of their own.

Drawing Objects

In ROOT, most objects derive from a base class TObject. This class has a virtual method Draw() so all objects are supposed to be able to be "drawn". The basic whiteboard on which an object is drawn is called a canvas (defined by the class TCanvas). If several canvases are defined, there is only one active at a time. One draws an object in the active canvas by using the statement:

\[ \text{object.Draw()} \]

This instructs the object "object" to draw itself. If no canvas is opened, a default one (named "c1") is instantiated and drawn. Try the following commands:

```
root[] tline a (0.1,0.1,0.6,0.6)
root[] a.Draw()
<TCanvas::MakeDefCanvas>: created default TCanvas with name c1
```

The first statement defines a line and the second one draws it. A default canvas is drawn since there was no opened one.

Interacting with Graphical Objects

When an object is drawn, one can interact with it. For example, the line drawn in the previous paragraph may be moved or transformed. One very important characteristic of ROOT is that transforming an object on the screen will also transform it in memory. One actually interacts with the real object, not with a copy of it on the screen. You can try for instance to look at the starting X coordinate of the line:

```
root[] a.GetX1()
(double)1.000000000e-1
```

X1 is the x value of the starting coordinate given in the definition above. Now move it interactively by clicking with the left mouse button in the line's middle and try to do again

```
root[] a.GetX1()
(Double_t)1.31756468483816005e-01
```

You do not obtain the same result as before, the coordinates of 'a' have changed. As said, interacting with an object on the screen changes the object in memory.

Moving, Resizing and Modifying Objects

Changing the graphic objects attributes can be done with the GUI or programmatically. First, let’s see how it is done in the GUI.

The Left Mouse Button

As was just seen moving or resizing an object is done with the left mouse button. The cursor changes its shape to indicate what may be done:

- Point the object or one part of it:
- Rotate:
- Resize (exists also for the other directions):
- Enlarge (used for text):
- Move:

Here are some examples of Moving:

Resizing:

Rotating:
With C++ Statements (Programmatically)

How would one move an object in a script? Since there is a tight correspondence between what is seen on the screen and the object in memory, changing the object changes it on the screen.

For example, try to do:

```c++
root[] a.SetX1(0.9)
```

This should change one of the coordinates of our line, but nothing happens on the screen. Why is that? In short, the canvas is not updated with each change for performance reasons. See the sub section on: "Updating the Pad" in the next section.

Selecting Objects

The Middle Mouse Button

Objects in a canvas, as well as in a pad, are stacked on top of each other in the order they were drawn. Some objects may become "active" objects, which means they are reordered to be on top of the others. To interactively make an object "active", you can use the middle mouse button. In case of canvases or pads, the border becomes highlighted when it is active.

With C++ Statements (Programmatically)

Frequently we want to draw in different canvases or pads. By default, the objects are drawn in the active canvas. To activate a canvas you can use the "TPad::cd()" method.

```c++
root[] c1->cd()
```

This picture shows that drawing a simple histogram involves as many as seven objects.

When selecting a method from the context menu and that method has options, the user will be asked for numerical values or strings to fill in the option. For example, `TAxis::SetTitle` will prompt you for a string to use for the axis title.

Structure of the Context Menus

The curious reader will have noticed that each entry in the context menu corresponds to a method of the class.

Look for example to the menu named `TAxis::xaxis`. `xaxis` is the name of the object and `TAxis` the name of its class. If we look at the list of `TAxis` methods, for example in `http://www.root.ch/root/html/TAxis.html`, we see the methods `SetTimeDisplay` and `UnZoom`, which appear also in the context menu.

Context Menus: the Right Mouse Button

The context menus are a way to interactively call certain methods of an object. When designing a class, the programmer can add methods to the context menu of the object by making minor changes to the header file.

Using Context Menus

On a ROOT canvas, you can right-click on any object and see the context menu for it. The script `hsimple.c` draws a histogram. The image below shows the context menus for some of the objects on the canvas.
There are several divisions in the context menu, separated by lines. The top division is a list of the class methods; the second division is a list of the parent class methods. The subsequent divisions are the methods other parent classes in case of multiple inheritance.

For example, see the TPrivate::title context menu. TPrivate inherits from TAttLine, which has the method SetLineAttributes().

### Adding Context Menus for a Class

A method to appear in the context menu of the object it has to be marked by `// *MENU*` in the header file. Below is the line from TAttLine.h that adds the SetLineAttributes method to the context menu.

```cpp
virtual void SetLineAttributes(); // *MENU*
```

Nothing else is needed, since CINT knows the classes and their methods. It takes advantage of that to create the context menu on the fly when the object is clicking on.

If you click on an axis, ROOT will ask the interpreter what are the methods of the TAxis and which ones are set for being displayed in a context menu.

Now, how does the interpreter know this? Remember, when you build a class that you want to use in the ROOT environment, you use `rootcint` that builds the so-called stub functions and the dictionary. These functions and the dictionary contain the knowledge of the used classes. To do this, `rootcint` parses all the header files.

ROOT has defined some special syntax to inform CINT of certain things; this is done in the comments so that the code still compiles with a C++ compiler.

For example, you have a class with a `Draw()` method, which will display itself. You would like a context menu to appear when on clicks on the image of an object of this class. The recipe is the following:

1. The class has to contain the `ClassDef/ClassImp` macros.
2. For each method you want to appear in the context menu, put a comment after the declaration containing `*MENU*` or `*TOGGLE*` depending on the behavior you expect. One usually uses `Set` methods (setters).

For example:

```cpp
class MyClass : public TObject
{
  int fV1; // first variable
  double fV2; // second variable

  private:
  int GetV1(); {return fV1;}
  double GetV2(); {return fV2;}

  public:
  void SetV1(int x1) { fV1 = x1; } // *MENU*
  void SetV2(double d2) { fV2 = d2; } // *MENU*
  void SetBoth(int x1, double d2) { fV1 = x1; fV2 = d2; }

  ClassDef(MyClass,1)
}
```

The `*TOGGLE*` comment is used to toggle a boolean data field. In that case, it is safe to call the data field `MyBool` where `MyBool` is the name of the setter `SetMyBool`. Replace `MyBool` with your own boolean variable.

3. You can specify arguments and the data members in which to store the arguments.

For example:

```cpp
void SetXXX(Int_t x1, Float_t y2); // *MENU* *ARGS={x1=>fV1, y2=>fV2}
```

This statement is in the comment field, after the `*MENU*`. If there is more than one argument, these arguments are separated by commas, where `fX1` and `fY2` are data fields in the same class.

```cpp
void SetXXX(Int_t x1, Float_t y2); // *MENU* *ARGS={x1=xV1, y2=yV2}
```

If the arguments statement is present, the option dialog displayed when selecting `SetXXX` will show the values of variables. We indicate to the system which argument corresponds to which data member of the class.

### Executing Events when a Cursor passes on top of an Object

This paragraph is for class designers. When a class is designed, it is often desirable to include drawing methods for it. We will have a more extensive discussion about this, but drawing an object in a canvas or a pad consists in "attaching" the object to that pad. When one uses `object.Draw()`, the object is NOT painted at this moment. It is only attached to the active pad or canvas.

Another method should be provided for the object to be painted, the `Paint()` method. This is all explained in the next paragraph.

As well as `Draw()` and `Paint()`, other methods may be provided by the designer of the class. When the mouse is moved or a button is pressed/released, the `TCanvas` function named `HandleInput()` scans the list of objects in all its pads and for each object calls some standard methods to make the object react to the event (mouse movement, click or whatever).

The second one is `DistanceToPrimitive(px, py)`. This function computes a "distance" to an object from the mouse position at the pixel position `(px, py)`, see definition at the end of this paragraph and returns this distance in pixel units. The selected object will be the one with the shortest computed distance. To see how this works, select the `Event Status` item in the canvas "Options" menu. ROOT will display one status line showing the picked object. If the picked object is, for example, a histogram, the status line indicates the name of the histogram, the position `x,y` in histogram coordinates, the channel number and the channel content.

It's nice for the canvas to know what is the closest object from the mouse, but it's even nicer to be able to make this object react. The third standard method to be provided is `ExecuteEvent()`. This method actually does the event reaction. Its prototype is where `px` and `py` are the coordinates at which the event occurred, except if the event is a key press, in which case `px` contains the key code.
void ExecuteEvent(Int_t event, Int_t px, Int_t py);

Where event is the event that occurs and is one of the following (defined in Buttons.h):

kNoEvent, kButton1Down, kButton2Down, kButton3Down,
kButton1Up, kButton2Up, kButton3Up, kButton1Motion,
kButton2Motion, kButton3Motion, kButton1Locate,
kButton2Locate, kButton3Locate, kButton1Double,
kButton2Double, kButton3Double, kKeyDown, kKeyUp,
KeyUp, kKeyPress, kMouseMotion, kMouseEnter, kMouseLeave.

We hope the names are self-explanatory.

Designing an ExecuteEvent method is not very easy, except if one wants very basic treatment. We will not go into that and let the reader refer to the sources of classes like TLine or TBox. Go and look at their ExecuteEvent method!

We can nevertheless give some reference to the various actions that may be performed. For example, one often wants to change the shape of the cursor when passing on top of an object. This is done with the SetCursor method:

gPad->SetCursor(cursor)

The argument cursor is the type of cursor. It may be:

kBottomLeft, kBottomRight, kTopLeft, kTopRight,
kBottomSide, kLeftSide, kTopSide, kRightSide, kMove,
xCross, kArrowHor, kArrowVer, kHand, kRotate, kPointer,
ARrowRight, kCaret, kWatch.

They are defined in TVirtualX.h and again we hope the names are self-explanatory. If not, try them by designing a small class. It may derive from something already known like TLine.

Note that the ExecuteEvent() functions may in turn, invoke such functions for other objects, in case an object is drawn using other objects. You can also exploit at best the virtues of inheritance. See for example how the class TArrow (derived from TLine) use or redefine the picking functions in its base class.

The last comment is that mouse position is always given in pixel units in all these standard functions. px=0 and py=0 corresponds to the top-left corner of the canvas. Here, we have followed the standard convention in windowing systems. Note that user coordinates in a canvas (pad) have the origin at the bottom-left corner of the canvas (pad). This is all explained in the paragraph "Coordinate system of a pad".

Graphical Containers: Canvas and Pad

We have talked a lot about canvases, which may be seen as windows. More generally, a graphical entity that contains graphical objects is called a Pad. A Canvas is a special kind of Pad. From now on, when we say something about pads, this also applies to canvases.

A pad (class TPad) is a graphical container in the sense it contains other graphical objects like histograms and arrows. It may contain other pads (sub-pads) as well. More technically, each pad has a linked list of pointers to the objects it holds.

Drawing an object is nothing more than adding its pointer to this list. Look for example at the code of TH1::Draw(). It is merely ten lines of code. The last statement is AppendPad(). This statement calls a method of TObject that just adds the pointer of the object, here a histogram, to the list of objects attached to the current pad. Since this is a TObject method, every object may be "drawn", which means attached to a pad.

We can illustrate this by the following figure.

The image correspond to this structure.
When is the painting done then? The answer is: when needed. Every object that derives from TObject has a Paint() method. It may be empty, but for graphical objects, this routine contains all the instructions to effectively paint it in the active pad. Since a Pad has the list of objects it owns, it will call successively the Paint() method of each object, thus re-painting the whole pad on the screen. If the object is a sub-pad, its Paint() method will call the Paint() method of the objects attached, recursively calling paint() for all the objects.

**The Global Pad: gPad**

When an object is drawn, it is always in the so-called active pad. For every day use, it is comfortable to be able to access the active pad, whatever it is. For that purpose, there is a global pointer, called gPad. It is always pointing to the active pad. If you want to change the fill color of the active pad to blue but you don't know its name, do this:

```cpp
root[] gPad->GetFillColor(38)
```

To get the list of colors, go to the paragraph "Color and color palettes" or if you have an opened canvas, click on the View menu, selecting the Colors item.

**Finding an Object in a Pad**

Now that we have a pointer to the active pad, gPad and that we know this pad contains some objects, it is sometimes interesting to access one of those objects. The method GetPrimitive() of TPad, i.e. TPad::GetPrimitive(const char* name) does exactly this. Since most of the objects that a pad contains derive from TObject, they have a name. The following statement will return a pointer to the object myobjectname and put that pointer into the variable obj. As you see, the type of returned pointer is (TObject*).

```cpp
root[] obj = gPad->GetPrimitive("myobjectname")
[class TObject*]0x1063cba8
```

Even if your object is something more complicated, like a histogram TH1F, this is normal. A function cannot return more than one type. So the one chosen was the lowest common denominator to all possible classes, the class from which everything derives, TObject.

How do we get the right pointer then?

Simply do a cast of the function output that is transforming this output (pointer) into the right type. For example if the object is a TPaveLabel:

```cpp
root[] obj = (TPaveLabel*)gPad->GetPrimitive("myobjectname")
[class TPaveLabel*]0x1063cba8
```

This works for all objects deriving from TObject. However, a question remains. An object has a name if it derives from TNamed, not from TObject. For example, an arrow (TArrow) doesn't have a name. In that case, the "name" is the name of the class. To know the name of an object, just click with the right button on it. The name appears at the top of the context menu.

In case of multiple unnamed objects, a call to GetPrimitive("className") returns the instance of the class that was first created. To retrieve a later instance you can use

```cpp
GetPrimitive("className")
```

GetPrimitive(), which returns a list of all the objects on the pad. From the list you can select the object you need.

**Hiding an Object**

Hiding an object in a pad can be made by removing it from the list of objects owned by that pad. This list is accessible by the GetListOfPrimitives() method of TPad. This method returns a pointer to a TList. Suppose we get the pointer to the object, we want to hide, call it obj (see paragraph above). We get the pointer to the list:

```cpp
root[] li = gPad->GetListOfPrimitives()
```

Then remove the object from this list:

```cpp
root[] li->Remove(obj)
```

The object will disappear from the pad as soon as the pad is updated (try to resize it for example).

If one wants to make the object reappear:

```cpp
root[] obj->Draw()
```

Caution, this will not work with composed objects, for example many histograms drawn on the same plot (with the option "same"). There are other ways! Try to use the method described here for simple objects.

**The Coordinate Systems of a Pad**

Three coordinate systems may be used in a TPad: pixel coordinates, normalized coordinates (NDC), and user coordinates.

**The User Coordinate System**

The most common is the user coordinate system. Most methods of TPad use the user coordinates, and all graphic primitives have their parameters defined in terms of user coordinates. By default, when an empty pad is drawn, the user coordinates are set to a range from 0 to 1 starting at the lower left corner. At this point they are equivalent of the NDC coordinates (see below). If you draw a high level graphical object, such as a histogram or a function, the user coordinates are set to the coordinates of the histogram. Therefore, when you set a point it will be in the histogram coordinates.
For a newly created blank pad, one may use `TPad::Range` to set the user coordinate system. This function is defined as:

```cpp
void Range(float x1, float y1, float x2, float y2)
```

The arguments `x1, x2` defines the new range in the x direction, and the `y1, y2` define the new range in the y-direction.

```cpp
root[] TCanvas MyCanvas("MyCanvas")
root[] gPad->Range(-100, -100, 100, 100)
```

This will set the active pad to have both coordinates to go from -100 to 100, with the center of the pad at (0,0). You can visually check the coordinates by viewing the status bar in the canvas. To display the status bar select `Options:Event Status` in the canvas menu.

### The Normalized Coordinate System (NDC)

Normalized coordinates are independent of the window size and of the user system. The coordinates range from 0 to 1 and (0,0) correspond to the bottom-left corner of the pad. Several internal ROOT functions use the NDC system (3D primitives, PostScript, log scale mapping to linear scale). You may want to use this system if the user coordinates are not known ahead of time.

### The Pixel Coordinate System

The least common is the pixel coordinate system, used by functions such as `DistanceToPrimitive()` and `ExecuteEvent()`. Its primary use is for cursor position, which is always given in pixel coordinates. If (px,py) is the cursor position, px=0 and py=0 corresponds to the top-left corner of the pad, which is the standard convention in windowing systems.

### Using NDC for a particular Object

Most of the time, you will be using the user coordinate system. But sometimes, you will want to use NDC. For example, if you want to draw text always at the same place over a histogram, no matter what the histogram coordinates are. There are two ways to do this. You can set the NDC for one object or may convert NDC to user coordinates. Most graphical objects offer an option to be drawn in NDC. For instance, a line (`TLine`) may be drawn in NDC by using `DrawLineNDC()`. A latex formula or a text may use `TText::SetNDC()` to be drawn in NDC coordinates.

### Converting between Coordinates Systems

There are a few utility functions in `TPad` to convert from one system of coordinates to another. In the following table, a point is defined by (px,py) in pixel coordinates; (ux,uy) in user coordinates, (ndcx,ndcy) in NDC coordinates.

<table>
<thead>
<tr>
<th>Conversion</th>
<th>Methods of TPad</th>
<th>Returns</th>
</tr>
</thead>
<tbody>
<tr>

<td>changes px,py</td>
</tr>
</tbody>
</table>

### Dividing a Pad into Sub-pads

Dividing a pad into sub pads in order for instance to draw a few histograms, may be done in two ways. The first is to build pad objects and to draw them into a parent pad, which may be a canvas. The second is to automatically divide a pad into horizontal and vertical sub pads.

### Creating a Single Sub-pad

The simplest way to divide a pad is to build sub-pads in it. However, this forces the user to explicitly indicate the size and position of those sub-pads. Suppose we want to build a sub-pad in the active pad (pointed by `gPad`).

First, we build it, using a `TPad` constructor:

```cpp
root[] subpad1 = new TPad("subpad1","The first subpad",.1,.1,.5,.5)
```

One gives the coordinates of the lower left point (0.1,0.1) and of the upper right one (0.5,0.5). These coordinates are in `NDC`. This means that they are independent of the user coordinates system, in particular if you have already drawn for example a histogram in the mother pad.

The only thing left is to draw the pad:

```cpp
root[] subpad1->Draw()
```

If you want more sub-pads, you have to repeat this procedure as many times as necessary.
Dividing a Canvas into Sub-Pads

The manual way of dividing a pad into sub-pads is sometimes very tedious. There is a way to automatically generate horizontal and vertical sub-pads inside a given pad.

```
root[] pad1->Divide(3,2)
```

If `pad1` is a pad then, it will divide the pad into 3 columns of 2 sub-pads:

The generated sub-pads get names `pad1_i` where `i` is 1 to `nxm`. In our case `pad1_1, pad1_2... pad1_6`:

The names `pad1_1` etc... correspond to new variables in CINT, so you may use them as soon as the `pad->Divide()` was executed. However, in a compiled program, one has to access these objects. Remember that a pad contains other objects and that these objects may, themselves be pads. We can use the `GetPrimitive()` method of `TPad`:

```
TPad* pad1_1 = (TPad*)(pad1->GetPrimitive("pad1_1"))
```

One question remains. In case one does an automatic divide, how can one set the default margins between pads? This is done by adding two parameters to `Divide()`, which are the margins in x and y:

```
root[] pad1->Divide(3,2,0.1,0.1)
```

The margins are here set to 10% of the parent pad width.

Updating the Pad

For performance reasons, a pad is not updated with every change. For example, changing the coordinates of the pad does not automatically redraw it. Instead, the pad has a "bit-modified" that triggers a redraw. This bit is automatically set by:

1. Touching the pad with the mouse. For example resizing it with the mouse.
2. Finishing the execution of a script.
3. Adding a new primitive or modifying some primitives for example the name and title of an object.

You can also set the "bit-modified" explicitly with the `Modified` method:

```
// this pad has changed
root[] pad1->Modified()
```

```
// recursively update all modified pads:
root[] c1->Update()
```

A subsequent call to `TCanvas->Update()` scans the list of sub-pads and repaints the pads declared modified.

In compiled code or in a long macro, you may want to access an object created during the paint process. To do so you can force the painting with a `TCanvas::Update()`. For example a `TGraph` creates a histogram (`TH1`) to paint itself. In this case the internal histogram obtained with `TGraph::GetHistogram()` is created only after the pad is painted. The pad is painted automatically after the script is finished executing or if you force the painting with `TPad::Modified` followed by a `TCanvas::Update().`

Note that it is not necessary to call `TPad::Modified` after a call to `Draw()`. The "bit-modified" is set automatically by `Draw()`.

A note about the "bit-modified" in sub pads: when you want to update a sub pad in your canvas, you need to call `pad->Modified` rather than canvas-`Modified` and follow it with a canvas-`Update`. If you use canvas-`Modified`,  followed by a call to canvas-`Update`, the sub pad has not been declared modified and it will not be updated.

Also note that a call to `pad->Update` where pad is a sub pad of canvas, calls canvas-`Update` and recursively updates all the pads on the canvas.

Making a Pad Transparent

As we will see in the paragraph "Fill attributes", a fill style (type of hatching) may be set for a pad.

```
// make pad1 transparent
root[] pad1->SetFillStyle(istyle)
```

This is done with the `SetFillStyle` method where `istyle` is a style number, defined in "Fill attributes".

A special set of styles allows handling of various levels of transparency. These are styles number 4000 to 4100, 4000 being fully transparent and 4100 fully opaque.

So, suppose you have an existing canvas with several pads. You create a new pad (transparent) covering for example the entire canvas. Then you draw your primitives in this pad.

The same can be achieved with the graphics editor.
For example:

```
root[] .x tutorials/h1draw.C
root[] TPad *newpad=new TPad("newpad","a transparent pad",0,0,1,1);
root[] newpad.SetFillStyle(4000);
root[] newpad.Draw();
root[] newpad.cd();
root[] // create some primitives, etc
```

### Setting the Log Scale is a Pad Attribute

Setting the scale to logarithmic or linear is an attribute of the pad, not the axis or the histogram. The scale is an attribute of the pad because you may want to draw the same histogram in linear scale in one pad and in log scale in another pad. Frequently, we see several histograms on top of each other in the same pad. It would be very inconvenient to set the scale attribute for each histogram in a pad. Furthermore, if the logic were in the histogram class (or each object), one would have to test for the scale setting in each the Paint methods of all objects.

If you have a pad with a histogram, a right-click on the pad, outside of the histograms frame will convince you. The `SetLogx()`, `SetLogy()` and `SetLogz()` methods are there. As you see, `TPad` defines log scale for the two directions $x$ and $y$ plus $z$ if you want to draw a 3D representation of some function or histogram.

The way to set log scale in the $x$ direction for the active pad is:

```
root[] gPad->SetLogx(1)
```

To reset log in the $z$ direction:

```
root[] gPad->SetLogz(0)
```

If you have a divided pad, you need to set the scale on each of the sub-pads. Setting it on the containing pad does not automatically propagate to the sub-pads. Here is an example of how to set the log scale for the $x$-axis on a canvas with four sub-pads:

```
root[] TCanvas MyCanvas("MyCanvas", "My Canvas")
root[] MyCanvas->Divide(2,2)
root[] MyCanvas->cd(1)
root[] gPad->SetLogx()  
root[] MyCanvas->cd(2)
root[] gPad->SetLogx()  
root[] MyCanvas->cd(3)
root[] gPad->SetLogx()  
```

### Graphical Objects

In this paragraph, we describe the various simple 2D graphical objects defined in ROOT. Usually, one defines these objects with their constructor and draws them with their `Draw()` method. Therefore, the examples will be very brief. Most graphical objects have line and fill attributes (color, width) that will be described in "Graphical objects attributes".

**If the user wants more information, the class names are given and he may refer to the online developer documentation. This is especially true for functions and methods that set and get internal values of the objects described here.**

By default 2D graphical objects are created in User Coordinates with 0,0 in the lower left corner.

### Lines, Arrows, and Geometrical Objects

**Line: Class TLine**

The simplest graphical object is a line. It is implemented in the `TLine` class. The constructor is:

```
TLine(Double_t x1, Double_t y1, Double_t x2, Double_t y2)
```

The arguments $x_1$, $y_1$, $x_2$, $y_2$ are the coordinates of the first and second point.

This constructor may be used as:

```
root[] l = new TLine(0.2,0.2,0.8,0.3)
root[] l->Draw()
```

**Arrows: Class TArrow**

Different arrow formats as show in the picture below are available.

Once an arrow is drawn on the screen, one can:

- click on one of the edges and move this edge.
- click on any other arrow part to move the entire arrow.

The constructor is:

```
TArrow(Double_t x1, Double_t y1,Double_t x2, Double_t y2, Float_t arrowsize, Option_t *option)
```

It defines an arrow between points $x_1,y_1$ and $x_2,y_2$. The arrow size is in percentage of the pad height.
The options are the following:

- option = ">"
- option = "<"
- option = "|>"
- option = "<|
- option = "<>"
- option = "<|"

If FillColor == 0, draw open triangle else draw full triangle with fill color.
If ar is an arrow object, fill color is set with:

```cpp
ar.SetFillColor(icolor);
```

Where icolor is the color defined in "Color and color palettes". The opening angle between the two sides of the arrow is 60 degrees. It can be changed with `ar->SetAngle(angle)`, where angle is expressed in degrees.

**Poly-line: Class TPolyLine**

A poly-line is a set of joint segments. It is defined by a set of N points in a 2D space. Its constructor is:

```cpp
TPolyLine(Int_t n, Double_t* x, Double_t* y, Option_t* option)
```

Where n is the number of points, and x and y are arrays of n elements with the coordinates of the points. `TPolyLine` can be used by itself, but is also a base class for other objects, such as curly arcs.

**Circles, Ellipses: Class TEllipse**

Ellipse is a general ellipse that can be truncated and rotated. An ellipse is defined by its center (x1, y1) and two radii r1 and r2. A minimum and maximum angle may be specified (phimin, phimax). The picture below illustrates different types of ellipses:

The Ellipse may be rotated with an angle theta. The attributes of the outline line and of the fill area are described in "Graphical objects attributes". The constructor of a `TEllipse` object is:

```cpp
TEllipse(Double_t x1, Double_t y1, Double_t r1, Double_t r2, Double_t phimin, Double_t phimax, Double_t theta)
```

An ellipse may be created with a statement like:

```cpp
root [] e = new TEllipse(0.2, 0.2, 0.8, 0.3)
root [] e->Draw()
```

**Rectangles: Classes TBox and TWbox**

A rectangle is defined by the class `TBox` since it is a base class for many different higher-level graphical primitives. A box is defined by its bottom left coordinates x1, y1 and its top right coordinates x2, y2.

The constructor being:

```cpp
TBox(Double_t x1, Double_t y1, Double_t x2, Double_t y2)
```

It may be used as in:

```cpp
root [] b = new TBox(0.2, 0.2, 0.8, 0.3)
root [] b->Draw()
```

A `TWbox` is a rectangle (`TBox`) with a border size and a border mode.

The attributes of the outline line and of the fill area are described in "Graphical Objects Attributes".
**One Point, or Marker: Class TMarker**

A marker is a point with a fancy shape! The possible markers are the following:

<table>
<thead>
<tr>
<th>Number</th>
<th>Shape</th>
</tr>
</thead>
<tbody>
<tr>
<td>20</td>
<td>●</td>
</tr>
<tr>
<td>21</td>
<td>■</td>
</tr>
<tr>
<td>22</td>
<td>▲</td>
</tr>
<tr>
<td>23</td>
<td>▼</td>
</tr>
<tr>
<td>24</td>
<td>○</td>
</tr>
<tr>
<td>25</td>
<td>□</td>
</tr>
<tr>
<td>26</td>
<td>△</td>
</tr>
<tr>
<td>27</td>
<td>▽</td>
</tr>
<tr>
<td>28</td>
<td>◇</td>
</tr>
<tr>
<td>29</td>
<td>●</td>
</tr>
<tr>
<td>30</td>
<td>■</td>
</tr>
<tr>
<td>1</td>
<td>❌</td>
</tr>
<tr>
<td>2</td>
<td>✗</td>
</tr>
<tr>
<td>3</td>
<td>✗</td>
</tr>
<tr>
<td>4</td>
<td>❌</td>
</tr>
<tr>
<td>5</td>
<td>✗</td>
</tr>
<tr>
<td>6</td>
<td>✗</td>
</tr>
<tr>
<td>7</td>
<td>❌</td>
</tr>
<tr>
<td>8</td>
<td>✗</td>
</tr>
<tr>
<td>9</td>
<td>✗</td>
</tr>
<tr>
<td>10</td>
<td>❌</td>
</tr>
<tr>
<td>11</td>
<td>✗</td>
</tr>
</tbody>
</table>

One marker is build via the constructor:

```cpp
TMarker(Double_t x, Double_t y, Int_t marker)
```

The parameters `x` and `y` are the coordinates of the marker and `marker` is the type, shown above.

Suppose `ma` is a valid marker. One can set the size of the marker with `ma->SetMarkerSize(size)`, where `size` is the desired size. The available sizes are:

- Sizes smaller than 1 may be specified.

**Set of Points: Class TPolyMarker**

A `TPolyMarker` is defined by an array of `N` points in a 2-D space. At each point `x[i]`, `y[i]` a marker is drawn. The list of marker types is shown in the previous paragraph.

The marker attributes are managed by the class `TAttMarker` and are described in "Graphical objects attributes"

The constructor for a `TPolyMarker` is:

```cpp
TPolyMarker(Int_t n, Double_t *x, Double_t *y, Option_t *option)
```

Where `x` and `y` are arrays of coordinates for the `n` points that form the polymarker.

**Curly and Wavy Lines for Feynman Diagrams**

This is a peculiarity of particle physics, but we do need sometimes to draw Feynman diagrams. Our friends working in banking can skip this part.

A set of classes implements curly or wavy poly-lines typically used to draw Feynman diagrams. Amplitudes and wavelengths may be specified in the constructors, via commands or interactively from context menus. These classes are `TCurlyLine` and `TCurlyArc`.

These classes make use of `TPolyLine` by inheritance; `ExecuteEvent` methods are highly inspired from the methods used in `TPolyLine` and `TAttMarker`.

The picture below has been generated by the tutorial `feynman.C`:

---

**Text and Latex Mathematical Expressions**

Text displayed in a pad may be embedded into boxes, called paves (such as `PaveLabels`), or titles of graphs or many other objects but it can live a life of its own. All text displayed in ROOT graphics is an object of class `TText`. For a physicist, it will be most of the time a `TLatex` expression (which derives from `TText`).

`TLatex` has been conceived to draw mathematical formulae or equations. Its syntax is very similar to the Latex one in mathematical mode.

**Subscripts and Superscripts**

Subscripts and superscripts are made with the `_` and `^` commands. These commands can be combined to make complicated subscript and superscript expressions. You may choose how to display subscripts and superscripts using the 2 functions `SetIndiceSize(Double_t)` and `SetLimitIndiceSize(Int_t)`.
Examples of what can be obtained using subscripts and superscripts:

<table>
<thead>
<tr>
<th>Expression</th>
<th>Gives</th>
</tr>
</thead>
<tbody>
<tr>
<td>$x^{2y}$</td>
<td>$x^{2y}$</td>
</tr>
<tr>
<td>$x_{(2y)}$</td>
<td>$x_{(2y)}$</td>
</tr>
</tbody>
</table>

Fractions

Fractions denoted by the / symbol are made in the obvious way. The \frac command is used for large fractions in displayed formula; it has two arguments: the numerator and the denominator. For example, this equation is obtained by following expression.

$$x = \frac{y+z/2}{y^2+1}$$

Roots

The \sqrt command produces the square ROOT of its argument; it has an optional first argument for other roots.

Example:

\[ \sqrt{10} \quad \sqrt[3]{10} \]

Delimiters

You can produce three kinds of proportional delimiters.

- \[ \{ .... \} \] or "a la" Latex #left[.....#right]: big square brackets
- \{ .... \} or #left{.....#right}: big curly brackets
- \[ .... \] or #left|.....#right|: big absolute value symbol
- \[ .... \] or #left(.....#right): big parenthesis

Greek Letters

The command to produce a lowercase Greek letter is obtained by adding a \ to the name of the letter. For an uppercase Greek letter, just capitalize the first letter of the command name.

<table>
<thead>
<tr>
<th>Greek Letter</th>

</tbody>
</table>

Changing Style in Math Mode

You can change the font and the text color at any moment using:

\[ \texttt{\#font[font-number]{...} and \#color[color-number]{...}} \]

Mathematical Symbols

\LaTeX can make mathematical and other symbols. A few of them, such as + and \>, are produced by typing the corresponding keyboard character. Others are obtained with the commands in the following table.

<table>
<thead>
<tr>
<th>Symbol</th>
<th>Command</th>
</tr>
</thead>
<tbody>
<tr>
<td>\leq</td>
<td>\leq</td>
</tr>
<tr>
<td>\neq</td>

</tr>
<tr>
<td>\Rightarrow</td>
<td>\Rightarrow</td>
</tr>
<tr>
<td>\Rightarrow</td>
<td>\Rightarrow</td>
</tr>
</tbody>
</table>

Accents, Arrows and Bars

Symbols in a formula are sometimes placed one above another. \LaTeX provides special commands for doing this.

- \wedge = wedge
- \vee = vee
- \top = top
- \bot = bottom
- \#hat{a} = hat
- \#check = check
- \#acute = acute
- \#grave = grave
- \#dot = dot
- \#ddot = double dot
- \#bar{a} = bar
- \#vec{a} = vec

Accents, Arrows and Bars

Symbols in a formula are sometimes placed one above another. \LaTeX provides special commands for doing this.

- \#hat{a} = hat
- \#check = inverted hat
- \#acute = acute
- \#grave = accent grave
- \#dot = derivative
- \#ddot = double derivative
- \#bar{a} = bar
- \#vec{a} = vec

Graphics and the Graphical User Interface
Example 1

The following script ($\texttt{ROOTSYS/tutorials/latex.C}$)

```cpp
{ 
    gROOT->Reset();
    TCanvas c1("c1","Latex",600,700);
    TLatex l;
    l.SetTextAlign(12);
    l.SetTextSize(0.04);
    l.DrawLatex(0.1,0.8,"1) C(x) = d \sqrt{\frac{2}{\lambda D}} \int^{x}_{0}\cos\left(\frac{\pi}{2}t^{2}\right)dt");
    l.DrawLatex(0.1,0.6,"2) C(x) = d \sqrt{\frac{2}{\lambda D}} \int^{x}\cos\left(\frac{\pi}{2}t^{2}\right)dt");
    l.DrawLatex(0.1,0.4,"3) R = |A|^2 = \frac{1}{2}(\frac{1}{2}+C(V))^{2} + \frac{1}{2}(\frac{1}{2}+S(V))^{2}");
    l.DrawLatex(0.1,0.2,"4) F(t) = \sum_{i=-\infty}^{\infty} A(i) \cos\left(\frac{i}{t+i}\right)");
}
```

The script makes this picture:

![Image](image1.png)

Example 2

The following script ($\texttt{ROOTSYS/tutorials/latex2.C}$)

```cpp
{ 
    gROOT->Reset();
    TCanvas c1("c1","Latex",600,700);
    TLatex l;
    l.SetTextAlign(23);
    l.SetTextSize(0.1);
    l.DrawLatex(0.5,0.95,"e^{+}e^{-}\rightarrow Z^{0} \rightarrow I\bar{I}, q\bar{q}");
    l.DrawLatex(0.5,0.75,"|\mathbf{a} \cdot \mathbf{b}| = \sum_{i=1}^{\infty} a_{i} b_{ij}");
    l.DrawLatex(0.5,0.5,"i (\partial_{\mu} \bar{\psi} \gamma^{\mu} + m \bar{\psi} = 0 \iff (\Box + m^{2}) \psi = 0");
    l.DrawLatex(0.5,0.3,"L_{em} = eJ_{em} A_{\mu} , J_{em} = \bar{I} \gamma_{\mu} I, M_{i} = A_{\mu} \tau_{i}^{\mu}");
    l.DrawLatex(0.5,0.1,"m^{2}(\bar{\psi} \gamma_{\mu} \psi) + m^{2} \bar{\psi} \psi = 0");
}
```

The result is the following picture:

![Image](image2.png)
Example 3

The following script ($ROOTSYS/tutorials/latex3.C$):

```c
{ gROOT->Reset(); TCanvas c1("c1"); TPadPad c1; TPaveText pt(.1,.5,.9,.9); pt.AddText("\#frac{2s}{\pi\alpha^{2}}\frac{d\sigma}{dcos#theta} (e^{+}e^{-} \rightarrow f#bar{f}) = "); pt.AddText("\left| \frac{1}{1 - \Delta#alpha} \right|^{2} (1+cos^{2}#theta + 4 \text{Re} \left\{ \frac{2}{1 - \Delta#alpha} #chi(s) \hat{g}_{\nu}^{e}\hat{g}_{\nu}^{f} (1 + cos^{2}#theta) + 2 #hat{g}_{a}^{e}\hat{g}_{a}^{f} cos#theta \right\} \right)"); pt.SetLabel("Born equation"); pt.Draw(); }
```

The result is the following picture:

![Born equation](image)

Text in Labels and TPaves

Text displayed in a pad may be embedded into boxes, called paves, or may be drawn alone. In any case, it is recommended to use a Latex expression, which is covered in the previous paragraph. Using TLatex is valid whether the text is embedded or not. In fact, you will use Latex expressions without knowing it since it is the standard for all the embedded text.

A pave is just a box with a border size and a shadow option. The options common to all types of paves and used when building those objects, are the following:

- Option = "T" Top frame
- Option = "B" Bottom frame
- Option = "R" Right frame
- Option = "L" Left frame
- Option = "NDC" x1,y1,x2,y2 are given in NDC
- Option = "ARC" corners are rounded

We will see the practical use of these options in the description of the more functional objects like TPaveLabels.

There are several categories of paves containing text:

**TPaveLabels**

TPaveLabels are panels containing one line of text. They are used for labeling. The constructor is:

```c
TPaveLabel<Double_t x1, Double_t y1, Double_t x2, Double_t y2, const char *label, Option_t *option>
```

Where (x1, y1) are the coordinates of the bottom left corner, (x2, y2) the coordinates of the upper right corner. "label" is the text to be displayed and "option" is the drawing option, described above. By default, the border size is 5 and the option is "bx".

If one wants to set the border size to some other value, one may use the SetBorderSize() method. For example, suppose we have a histogram, which limits are (-100, 100) in the x direction and (0,1000) in the y direction.

The following lines will draw a label in the center of the histogram, with no border. If one wants the label position to be independent of the histogram coordinates, or user coordinates, one can use the option "NDC". See the paragraph about coordinate systems for more information.

```c
root[] pl = new TPaveLabel(-50, 0, 50,200,"Some text")
root[] pl->SetBorderSize(0)
root[] pl->Draw();
```
Here are examples of what may be obtained:

This is a PaveLabel with option TL
This is a PaveLabel with option TR
This is a PaveLabel with option BL
This is a PaveLabel with option BR

**TPaveText**

A TPaveText can contain only one line of text. A TPaveText may contain several lines. This is the only difference. This picture illustrates and explains some of the points of TPaveText. Once a TPaveText is drawn, a line can be added or removed by bring up the context menu with the mouse.

**TPavesText**

A TPavesText is a stack of text panels (see TPaveText). One can set the number of stacked panels at building time. The constructor is:

```
TPavesText(Double_t x1, Double_t y1, Double_t x2, Double_t y2, Int_t npaves, Option_t* option)
```

By default, the number of stacked panels is 5 and option = "br"

**Sliders**

Sliders may be used for showing the evolution of a process or setting the limits of an object's value interactively. A TSlider object contains a slider box that can be moved or resized. Slider drawing options include the possibility to change the slider starting and ending positions or only one of them.

The current slider position can be retrieved via the functions `TSlider::GetMinimum()` and `TSlider::GetMaximum()`. These two functions return numbers in the range [0,1].

One may set a C expression to be executed when the mouse button 1 is released. This is done with the `TSlider::SetMethod()` function. It is also possible to reference an object. If no method or C expression has been set, and an object is referenced (SetObject has been called), while the slider is being moved/resized, the object ExecuteEvent function is called.
Let's see an example using `SetMethod`. The script is called `xyslider.C`. You can find this script in `$ROOTSYS/tutorials`.

```c
// Example of script featuring two sliders
TFile *f = new TFile("hsimple.root");
TH2F *hxpy = (TH2F*)f->Get("hxpy");
TCanvas *c1 = new TCanvas("c1");
TPad *pad = new TPad("pad", "lego pad",
    0.1,0.1,0.98,0.98);
pad->SetFillColor(33);
pad->Draw();
pad->cd();
gStyle->SetFrameFillColor(42);
hxpy->SetFillColor(46);
hxpy->Draw("lego1");
c1->cd();

// Create two sliders in main canvas. When button1
// of the mouse will be released, action.C will be called
TSlider *xslider = new TSlider
    ("xslider","x",.1,.02,.98,.08);
xslider->SetMethod(".x action.C");
TSlider *yslider = new TSlider
    ("yslider","y",.02,.1,.06,.98);
yslider->SetMethod(".x action.C");
```

The script that is executed when button 1 is released is the following (script `action.C`):

```c
Int_t nx = hxpy->GetXaxis()->GetNbins();
Int_t ny = hxpy->GetYaxis()->GetNbins();
Int_t binxmin = nx*xslider->GetMinimum();
Int_t binxmax = nx*xslider->GetMaximum();
hxpy->GetXaxis()->SetRange(binxmin,binxmax);
Int_t binymin = ny*yslider->GetMinimum();
Int_t binymax = ny*yslider->GetMaximum();
hxpy->GetYaxis()->SetRange(binymin,binymax);
pad->cd();
hxpy->Draw("lego1");
c1->cd();
```

The canvas and the sliders created in the above script are shown in the picture below.

The second example uses `SetObject` (script `xyslider.C`). Same example as above but using the `SetMethod`:

```c
Myclass *obj = new Myclass();
// Myclass derived from TObject
xslider->SetObject(obj);
yslider->SetObject(obj);
```

When one of the sliders will be changed, `Myclass::ExecuteEvent()` will be called with `px=0` and `py = 0`.

### Axis

The axis objects are automatically built by various high level objects such as histograms or graphs. Once build, one may access them and change their characteristics. It is also possible, for some particular purposes to build axis on their own. This may be useful for example in the case one wants to draw two axis for the same plot, one on the left and one on the right.

For historical reasons, there are two classes representing axis. `TAxis` is the axis object, which will be returned when calling the `TH1::GetAxis()` method.

```c
TAxis *axis = histo->GetAxis();
```

Of course, you may do the same for `Y` and `Z`-axis.

The graphical representation of an axis is done with the `TGaxis` class. Instances of this class are generated by the histogram classes and `TGraph`. This is internal and the user should not have to see it.

### Axis Title

The axis title is set, as with all named objects, by

```c
axis->SetTitle("Whatever title you want");
```

When the axis is embedded into a histogram or a graph, one has to first extract the axis object:

```c
h->GetXaxis()->SetTitle("Whatever title you want");
```
Axis Options and Characteristics

The axis options are most simply set with the styles. The available style options controlling specific axis options are the following:

```
TAxis *axis = histo->GetXaxis();
axis->SetAxisColor(Color_t color = 1);
axis->SetLabelColor(Color_t color = 1);
axis->SetLabelFont(Style_t font = 62);
axis->SetLabelOffset(Float_t offset = 0.005);
axis->SetLabelSize(Float_t size = 0.04);
axis->SetNdivisions(Int_t n = 510, Bool_t optim = kTRUE);
axis->SetNoExponent(Bool_t noExponent = kTRUE);
axis->SetTickLength(Float_t length = 0.03);
axis->SetTitleOffset(Float_t offset = 1);
axis->SetTitleSize(Float_t size = 0.02);
```

The getters corresponding to the described setters are also available. Furthermore, the general options, not specific to axis, as for instance `SetTitleTextColor()` are valid and do have an effect on axis characteristics.

Setting the Number of Divisions

To set the number of divisions for an axis use:

```
TAxis::SetNdivisions(ndiv, optim)
```

where `ndiv` and `optim` are as follows:

- `ndiv` = `N1 + 100*N2 + 10000*N3`
  - `N1` = number of first divisions.
  - `N2` = number of secondary divisions.
  - `N3` = number of tertiary divisions.
- `optim` = `kTRUE` (default), the number of divisions will be optimized around the specified value.
- `optim` = `kFALSE`, or `n < 0`, the axis will be forced to use exactly `n` divisions.

For example:

- `ndiv = 0` : no tick marks.
- `ndiv = 2` : 2 divisions, one tick mark in the middle of the axis.
- `ndiv = 510` : 10 primary divisions, 5 secondary divisions
- `ndiv = -10` : exactly 10 primary divisions

Zooming the Axis

You can use `TAxis::SetRange` or `TAxis::SetRangeUser` to zoom the axis.

```
TAxis::SetRange(Int_t binfirst, Int_t binlast)
```

The SetRange method parameters are bin numbers. They are not axis. For example if a histogram plots the values from 0 to 500 and has 100 bins, SetRange(0,10) will cover the values 0 to 50.
Label Position
Labels are normally drawn on side opposite to tick marks. However, chopt = '=': on Equal side

Label Orientation
Labels are normally drawn parallel to the axis. However, if xmin = xmax, then they are drawn orthogonal, and if ymin = ymax they are drawn parallel.

Labels for Exponents
By default, an exponent of the form 10^N is used when the label values are either all very small or very large. One can disable the exponent by calling:

```
TAxis::SetNoExponent(kTRUE)
```

Note that this option is implicitly selected if the number of digits to draw a label is less than the `fgMaxDigits` global member.

If you have set the property `SetNoExponent` in TAxis (via TAxis::SetNoExponent(...), TAxis will inherit this property. TAxis is the class responsible for drawing the axis.

`SetNoExponent` is also available from the axis context menu.

Tick Mark Label Position
Labels are centered on tick marks. However, if xmin = xmax, then they are right adjusted.

- chopt = 'L': labels are left adjusted on tick mark (default is centered)
- chopt = 'R': labels are right adjusted on tick mark
- chopt = 'C': labels are centered on tick mark.
- chopt = 'M': In the Middle of the divisions.

Label Formatting
Blank characters are stripped, and then the label is correctly aligned. The dot, if last character of the string, is also stripped. In the following, we have some parameters, like tick marks length and characters height (in percentage of the length of the axis, in user coordinates)

The default values are as follows:

- Primary tick marks: 3.0 %
- Secondary tick marks: 1.5 %
- Third order tick marks: .75 %
- Characters height for labels: 4%
- Labels offset: 1.0 %

Stripping Decimals
Use the `TStyle::SetStripDecimals` to strip decimals when drawing axis labels. By default, the option is set to true, and `TGAxis::PaintAxis()` removes trailing 0s after a dot in the axis labels, e.g.: {0, 0.5, 1, 1.5, 2, 2.5,...}

```
TStyle::SetStripDecimals(Bool_t strip=kTRUE)
```

If this function is called with strip=kFALSE, `TGAxis::PaintAxis()` will draw labels with the same number of digits after the dot, e.g.: (0.0, 0.5, 1.0, 1.5, 2.0, 2.5,...)

Optional Grid
chopt = 'W': cross-Wire

Axis Binning Optimization
By default, the axis binning is optimized.

- chopt = 'N': No binning optimization
- chopt = 'I': Integer labeling
Time Format

Axis labels may be considered as times, plotted in a defined time format. The format is set with SetTimeFormat().

chopt = 't': Plot times with a defined format instead of values

The format string for date and time use the same options as the one used in the standard strftime C function.

For the date:

• %a abbreviated weekday name
• %b abbreviated month name
• %d day of the month (01-31)
• %m month (01-12)
• %y year without century

For the time:

• %H hour (24-hour clock)
• %I hour (12-hour clock)
• %p local equivalent of AM or PM
• %M minute (00-59)
• %S seconds (00-61)
• % %

The start time of the axis will be wmin + time offset. This time offset is the same for all axes, since it is gathered from the active style. One may set the time offset:

```
gStyle->SetTimeOffset(time)
```

Where "time" is the offset time expressed in UTC (Universal Coordinated Time) and is the number of seconds since a standard date (1970), adjusted for some earth's rotation drifting. Your computer time is using UTC as a reference.

Axis Example 1:

To illustrate all what was said before, we can show two scripts. This example creates this picture:
Axis Example 2:

The second example shows the use of the second form of the constructor, with axis ticks position determined by a function TF1:

```c
Axis Example with Time display:

// strip chart example
void seism() {
    TStopwatch sw; sw.Start();
    // set time offset
    TDatime dtime; gStyle->SetTimeOffset(dtime.Convert());
    TCanvas *c1 = new TCanvas("c1","Time on axis",10,10,1000,500);
    c1->SetFillColor(42);
    c1->SetFrameFillColor(33);
    c1->SetGrid();
    Float_t bintime = 1;
    // one bin = 1 second. change it to set the time scale
    TH1F *ht = new TH1F("ht","The ROOT seism",10,0,10*bintime);
    Float_t signal = 1000;
    ht->SetMaximum(signal);
    ht->SetMinimum(-signal);
    ht->SetStats(0);
    ht->SetLineColor(2);
    ht->GetXaxis()->SetTimeDisplay(1);
    ht->GetYaxis()->SetNdivisions(520);
    ht->Draw();
    for (Int_t i=1;i<2300;i++) {
        //======= Build a signal : noisy damped sine ======
        Float_t noise  = gRandom->Gaus(0,120);
        if (i > 700) noise += signal*sin((i-700.)*6.28/30)*exp((700.-i)/300.);
        ht->SetBinContent(i,noise);
        c1->Modified();
        c1->Update();
        gSystem->ProcessEvents();
    }
    printf("Real Time = %8.3fs, Cpu Time = %8.3fs\n",sw.RealTime(),sw.CpuTime());
}
```
Graphical Objects Attributes

Text Attributes
When a class contains text or derives from a text class, it needs to be able to set text attributes like font type, size, and color. To do so, the class inherits from the TAttText class (a secondary inheritance), which defines text attributes. TLatex and TText inherit from TAttText.

Setting Text Attributes Interactively
When clicking on an object containing text, one of the last items in the context menu is SetTextAttributes. Selecting it makes the following window appear:

This canvas allows you to set:

- The text alignment
- Font
- Color
- Size

Setting Text Alignment
Text alignment may also be set by a method call. What is said here applies to all objects deriving from TAttText, and there are many. We will take an example that may be transposed to other types. Suppose "la" is a TLatex object. The alignment is set with:

```c++
root[] la->SetTextAlign(align)
```

The parameter `align` is a short describing the alignment:

- `align = 10 * HorizontalAlign + VerticalAlign`

For Horizontal alignment the following convention applies:

- `1 = left`
- `2 = centered`
- `3 = right`

For Vertical alignment the following convention applies:

- `1 = bottom`
- `2 = centered`
- `3 = top`

For example

Align: 11 = left adjusted and bottom adjusted
Align: 32 = right adjusted and vertically centered

Setting Text Angle
Use TAttText::SetTextAngle to set the text angle. The angle is the degrees of the horizontal.

```c++
root[] la->SetTextAngle(angle)
```

Setting Text Color
Use TAttText::SetTextColor to set the text color. The color is the color index. The colors are described in "Color and color palettes".

```c++
root[] la->SetTextColor(color)
```

Setting Text Font
Use TAttText::SetTextFont to set the font. The parameter font is the font code, combining the font and precision:

```c++
font = 10 * fontID + precision
```

The table below lists the available fonts. The font IDs must be between 1 and 14.

The precision can be:

- Precision = 0 fast hardware fonts (steps in the size)
• Precision = 1 scalable and rotate-able hardware fonts (see below)
• Precision = 2 scalable and rotate-able hardware fonts

When precision 0 is used, only the original non-scaled system fonts are used. The fonts have a minimum (4) and maximum (37) size in pixels. These fonts are fast and are of good quality. Their size varies with large steps and they cannot be rotated.

Precision 1 and 2 fonts have a different behavior depending if True Type Fonts (TTF) are used or not. If TTF are used, you always get very good quality scalable and rotate-able fonts. However, TTF are slow.

Precision 1 and 2 fonts have a different behavior for PostScript in case of TLatex objects:

• With precision 1, the PostScript text uses the old convention (see TPostScript) for some special characters to draw sub and superscripts or Greek text.
• With precision 2, the "PostScript" special characters are drawn as such. To draw sub and superscripts it is highly recommended to use TLatex objects instead.

For example: font = 62 is the font with ID 6 and precision 2

The available fonts are:

<table>
<thead>
<tr>
<th>Font ID</th>
<th>X11 True Type name</th>
<th>is italic</th>
<th>&quot;boldness&quot;</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>&quot;Times New Roman&quot;</td>
<td>Yes</td>
<td>4</td>
</tr>
<tr>
<td>2</td>
<td>&quot;Times New Roman&quot;</td>
<td>No</td>
<td>7</td>
</tr>
<tr>
<td>3</td>
<td>&quot;Times New Roman&quot;</td>
<td>Yes</td>
<td>7</td>
</tr>
<tr>
<td>4</td>
<td>&quot;Arial&quot;</td>
<td>No</td>
<td>4</td>
</tr>
<tr>
<td>5</td>
<td>&quot;Arial&quot;</td>
<td>Yes</td>
<td>4</td>
</tr>
<tr>
<td>6</td>
<td>&quot;Arial&quot;</td>
<td>No</td>
<td>7</td>
</tr>
<tr>
<td>7</td>
<td>&quot;Arial&quot;</td>
<td>Yes</td>
<td>7</td>
</tr>
<tr>
<td>8</td>
<td>&quot;Courier New&quot;</td>
<td>No</td>
<td>4</td>
</tr>
<tr>
<td>9</td>
<td>&quot;Courier New&quot;</td>
<td>Yes</td>
<td>4</td>
</tr>
<tr>
<td>10</td>
<td>&quot;Courier New&quot;</td>
<td>No</td>
<td>7</td>
</tr>
<tr>
<td>11</td>
<td>&quot;Courier New&quot;</td>
<td>Yes</td>
<td>7</td>
</tr>
<tr>
<td>12</td>
<td>&quot;Symbol&quot;</td>
<td>No</td>
<td>6</td>
</tr>
<tr>
<td>13</td>
<td>&quot;Times New Roman&quot;</td>
<td>No</td>
<td>4</td>
</tr>
<tr>
<td>14</td>
<td>&quot;Wingdings&quot;</td>
<td>No</td>
<td>4</td>
</tr>
</tbody>
</table>

Here is an example of what the fonts look like:

```
This script makes the image of the different fonts:

ID 1: The quick brown fox is not here anymore
ID 2: The quick brown fox is not here anymore
ID 3: The quick brown fox is not here anymore
ID 4: The quick brown fox is not here anymore
ID 5: The quick brown fox is not here anymore
ID 6: The quick brown fox is not here anymore
ID 7: The quick brown fox is not here anymore
ID 8: The quick brown fox is not here anymore
ID 9: The quick brown fox is not here anymore
ID 10: The quick brown fox is not here anymore
ID 11: The quick brown fox is not here anymore
ID 12: The quick brown fox is not here anymore
ID 13: The quick brown fox is not here anymore
ID 14: The quick brown fox is not here anymore
```

How to use True Type Fonts

You can activate the True Type Fonts by adding the following line in your .rootrc file:

```
Unix.*.Root.UseTTFonts: true
```

You can check that you indeed use the TTF in your Root session. When the TTF is active, you get the following message at the start of a session:

"Free Type Engine v1.x used to render TrueType fonts."

You can also check with the command:

```
gEnv->Print()
```
Setting Text Size

Use TAttText::SetTextSize to set the text size.

\[
\text{root[]} \ la->\text{SetTextSize(size)}
\]

The size is the text size expressed in percentage of the current pad size. The text size in pixels will be:

- If current pad is horizontal, the size in pixels = textsize * canvas_height
- If current pad is vertical, the size in pixels = textsize * canvas_width

Line Attributes

All classes manipulating lines have to deal with line attributes. This is done by using secondary inheritance of the class TAttLine.

Setting Line Attributes Interactively

When clicking on an object being a line or having some line attributes, one of the last items in the context menu is SetLineAttributes. Selecting it makes the following window appear:

This canvas allows you to set:

- The line color
- Style
- Width

Setting Line Color

Line color may be set by a method call. What is said here applies to all objects deriving from TAttLine, and there are many (histograms, plots). We will take an example that may be transposed to other types. Suppose "li" is a TLine object. The line color is set with:

\[
\text{root[]} \ li->\text{SetLineColor(color)}
\]

The argument color is a color number. The colors are described in "Color and Color Palettes"

Setting Line Style

Line style may be set by a method call. What is said here applies to all objects deriving from TAttLine, and there are many (histograms, plots). We will take an example that may be transposed to other types. Suppose "li" is a TLine object. The line style is set with:

\[
\text{root[]} \ li->\text{SetLineStyle(style)}
\]

The argument style is one of:
1=solid, 2=dash, 3=dash-dot, 4=dot-dot.

Setting Line Width

Line width may be set by a method call. What is said here applies to all objects deriving from TAttLine, and there are many (histograms, plots). We will take an example that may be transposed to other types. Suppose "li" is a TLine object. The line width is set with:

\[
\text{root[]} \ li->\text{SetLineWidth(width)}
\]

The width is the width expressed in pixel units.

Fill Attributes

Almost all graphics classes have a fill area somewhere. These classes have to deal with fill attributes. This is done by using secondary inheritance of the class TAttFill.

Setting Fill Attributes interactively

When clicking on an object having a fill area, one of the last items in the context menu is SetFillAttributes. Selecting it makes the following window appear:

This canvas allows you to set:

- The fill color
- Style

**Fill Color**

Fill color may be set by a method call. What is said here applies to all objects deriving from TAttFill, and there are many (histograms, plots). We will take an example that may be transposed to other types. Suppose "h" is a TH1F (1 dim histogram) object. The histogram fill color is set with:

```c
root[] h->SetFillColor(color)
```

The `color` is a color number. The colors are described in "Color and color palettes".

**Setting Fill Style**

Fill style may be set by a method call. What is said here applies to all objects deriving from TAttFill, and there are many (histograms, plots). We will take an example that may be transposed to other types. Suppose "h" is a TH1F (1 dim histogram) object. The histogram fill style is set with:

```c
root[] h->SetFillStyle(style)
```

The convention for `style` is:

- 0: hollow
- 1001: solid
- 2001: hatch style
- 3000 + pattern number: patterns
- 4000 to 4100: transparency, 4000 = fully transparent, 4100 = fully opaque.

The various patterns are represented here:

![Fill styles](image)

**Color and Color Palettes**

At initialization time, a table of basic colors is generated when the first Canvas constructor is called. This table is a linked list, which can be accessed from the `gROOT` object (see `TROOT::GetListOfColors()`).

Each color has an index and when a basic color is defined, two "companion" colors are defined:

- The dark version (color_index + 100)
- The bright version (color_index + 150)

The dark and bright colors are used to give 3-D effects when drawing various boxes (see `TWbox`, `TPave`, `TPaveText`, `TPaveLabel`, etc).

If you have a black and white copy of the manual, here are the basic colors and their indices:

- 1 = black
- 2 = red
- 3 = bright green
- 4 = bright blue
- 5 = yellow
- 6 = hot pink
- 7 = aqua
- 8 = green
- 9 = blue

0 -> 9: basic colors

10 -> 19: shades of gray
20 -> 29: shades of brown
30 -> 39: shades of blue
40 -> 49: shades of red

The list of currently supported basic colors (here dark and bright colors are not shown) is shown in the picture below:

The color numbers specified in the basic palette, and the picture above, can be viewed by selecting the item "Colors" in the "View" menu of the canvas toolbar.

Other colors may be defined by the user. To do this, one has to build a new object of type TColor, which constructor is:

```c
TColor(Int_t color, Float_t r, Float_t g, Float_t b, const char* name)
```

One has to give the color number and the three Red, Green, Blue values, each being defined from 0 (min) to 1 (max). An optional name may be given. When built, this color is automatically added to the existing list of colors.

If the color number already exists, one has to extract it from the list and redefine the RGB values. This may be done for example with:

```c
root[] color = (TColor*)(gROOT->GetListOfColors()->At(index_color))
root[] color->SetRGB(r,g,b)
```

Where `r`, `g` and `b` go from 0 to 1 and `index_color` is the color number you wish to change.

**Color Palette (for Histograms)**

Defining one color at a time may be tedious. The color palette is used by the histogram classes (see Draw Options). For example, `TH1::Draw("col")` draws a 2-D histogram with cells represented by a box filled with a color \( CI \) function of the cell content. If the cell content is \( n \), the color \( CI \) used will be...
The Graphical Editor

ROOT has a built-in graphics editor to draw and edit graphic primitives starting from an empty canvas or on top of a picture (e.g. histogram). The editor is started by selecting the "Editor" item in the canvas "Edit" menu. A menu appears into an independent window.

You can create the following graphical objects:
- **An arc or circle**: Click on the center of the arc, and then move the mouse. A rubber band circle is shown. Click again with the left button to freeze the arc.
- **A line or an arrow**: Click with the left button at the point where you want to start the arrow, then move the mouse and click again with the left button to freeze the arrow.
- **A Diamond**: Click with the left button and freeze again with the left button. The editor draws a rubber band box to suggest the outline of the diamond.
- **An Ellipse**: Proceed like for an arc. You can grow/shrink the ellipse by pointing to the sensitive points. They are highlighted. You can move the ellipse by clicking on the ellipse, but not on the sensitive points. If, with the ellipse context menu, you have selected a fill area color, you can move a filled-ellipse by pointing inside the ellipse and dragging it to its new position.

For example, to set the current palette to the "pretty" one, one has to do:

```c++
TStyle::SetPalette(1)
```

A more complete example is shown below. It illustrates the definition of a custom palette. You can adapt it to suit your needs. In case you use it for contour coloring, with the current color/contour algorithm, always define two more colors than the number of contours.

```c++
void palette()
{
  // Example of creating new colors (purples)
  // and defining of a new palette
  const Int_t colNum = 10;
  Int_t palette[colNum];
  for (Int_t i=0; i<colNum; i++) {
    // get the color and
    // if it does not exist create
    if (! gROOT->GetColor(230+i) ) {
        TColor *color = gROOT->GetColor(230+i);
        color->SetRGB(1-(i/((colNum)*1.0)),0.3,0.5);
    } else {
        TColor *color = gROOT->GetColor(230+i);
        color->SetRGB(1-(i/((colNum)*1.0)),0.3,0.5);
    }
    palette[i] = 230+i;
  }
  gStyle->SetPalette(colNum,palette);
}
```

The current color palette does not have a class or global object of it's own. It is defined in the current style as an array of color numbers. One may change the current palette with the `TStyle::SetPalette(Int_t ncolors, Int_t* color_indexes)` method.

By default, or if `ncolors <= 0`, a default palette (see above) of 50 colors is defined. The colors defined in this palette are good for coloring pads, labels, and other graphic objects.

If `ncolors > 0` and `colors = 0`, the default palette is used with a maximum of `ncolors` colors. If `ncolors <= 0` and `colors = 0`, then a pretty palette with a spectrum Violet->Red is created. It is recommended to use this pretty palette when drawing legos, surfaces or contours.

For example, to set the current palette to the "pretty" one, one has to do:

```c++
void palette()
{
  // Example of creating new colors (purples)
  // and defining of a new palette
  const Int_t colNum = 10;
  Int_t palette[colNum];
  for (Int_t i=0; i<colNum; i++) {
    // get the color and
    // if it does not exist create
    if (! gROOT->GetColor(230+i) ) {
        TColor *color = gROOT->GetColor(230+i);
        color->SetRGB(1-(i/((colNum)*1.0)),0.3,0.5);
    } else {
        TColor *color = gROOT->GetColor(230+i);
        color->SetRGB(1-(i/((colNum)*1.0)),0.3,0.5);
    }
    palette[i] = 230+i;
  }
  gStyle->SetPalette(colNum,palette);
}
```

You can move the ellipse by clicking on the ellipse, but not on the sensitive points. If, with the ellipse context menu, you have selected a fill area color, you can move a filled-ellipse by pointing inside the ellipse and dragging it to its new position.

Using the context menu, you can build an arc of ellipse and tilt the ellipse.

**A Pad**: Click with the left button and freeze again with the left button. The editor draws a rubber band box to suggest the outline of the pad.

**A Pave Label**: Proceed like for a pad. Type the text to be put in the box. Then type a carriage return. The text will be redrawn to fill the box.

**A Pave Text or Paves Text**: Proceed like for a pad. You can then click on the `TPaveText` object with the right mouse button and select the option AddText.

- **A Poly Line**: Click with the left button for the first point, move the mouse, click again with the left button for a new point. Close the poly-line with a double click. To edit one vertex point, pick it with the left button and drag to the new point position.
- **A CurlyLine**: Proceed as for the arrowline. Once done, click with the third button to change the characteristics of the curly line, like transform it to wave, change the wavelength, etc...
- **A CurlyArc**: Proceed like for the arrowline. The first click is located at the position of the center, the second click at the position of the arc beginning. Once done, one obtains a curly ellipse, for which one can click with the third button to change the characteristics, like transform it to wavy, change the wavelength, set the minimum and maximum angle to make an arc that is not closed, etc...
- **A Text /Latex string**: Click with the left button where you want to draw the text, then type in the text terminated by carriage return. All `TLatex` expressions are valid. To move the text or formula, point on it keeping the left
mouse button pressed and drag the text to its new position. You can
grow/shrink the text if you position the mouse to the first top-third part of the
string, then move the mouse up or down to grow or shrink the text
respectively. If you position the mouse near the bottom-end of the text, you
can rotate it.
A Marker: Click with the left button where to place the marker. The marker
can be modified by gStyle->SetMarkerStyle().
A Graphical Cut: Click with the left button on each point of a polygon
delimiting the selected area. Close the cut by double clicking on the last
point. A TCutG object is created. It can be used as a selection for a
TTree::Draw. You can get a pointer to this object with TCutG cut =
(TCutG*) gPad->GetPrimitive("CUTG").

Once you are happy with your picture, you can select the Save as
canvas.C item in the canvas File menu. This will automatically generate a
script with the C++ statements corresponding to the picture. This facility also
works if you have other objects not drawn with the graphics editor
(histograms for example).

Copy/Paste With DrawClone
You can make a copy of a canvas using TCanvas::DrawClonePad. This
method is unique to TCanvas. It clones the entire canvas to the active pad.
There is a more general method TObject::DrawClone, which all objects
descendants of TObject, specifically all graphic objects inherit. Below are
two examples, one to show the use of DrawClonePad and the other to show
the use of DrawClone.

Example 1: TCanvas::DrawClonePad
In this example we will copy an entire canvas to a new one with
DrawClonePad.
Run the script draw2dopt.C.

```
root [] .x tutorials/draw2dopt.C
```

This creates a canvas with 2D histograms. To make a copy of the canvas
follows these steps
Right-click on it to bring up the context menu.
Select DrawClonePad.
This copies the entire canvas and all its sub-pads to a new canvas. The
copied canvas is a deep clone, and all the objects on it are copies and
independent of the original objects. For instance, change the fill on one of the
original histograms, and the cloned histogram retains its attributes.
DrawClonePad will copy the canvas to the active pad; the target does not
have to be a canvas. It can also be a pad on a canvas.

Example 2: TObject::DrawClone
If you want to copy and paste a graphic object from one canvas or pad to
another canvas or pad, you can do so with DrawClone method inherited
from TObject. The TObject::DrawClone method is inherited by all
graphics objects.
In this example, we create a new canvas with one histogram from each of the
canvases from the script draw2dopt.C.

1. Start a new ROOT session and execute the script draw2dopt.C
2. Select a canvas displayed by the script, and create a new canvas from
   the File menu (c1).
3. Make sure that the target canvas (c1) is the active one by middle
   clicking on it. If you do this step right after step 2, c1 will be active.
4. Select the pad with the first histogram you want to copy and paste.
5. Right click on it to show the context menu, and select DrawClone.
6. Leave the option blank and hit OK.

Repeat these steps for one histogram on each of the canvases created by
the script, until you have one pad from each type.
If you wanted to put the same annotation on each of the sub pads in the new canvas, you could use DrawClone to do so. Here we added the date to each pad. The steps to this are:

1. Create the label in one of the pads with the graphics editor.
2. Middle-click on the target pad to make it the active pad
3. Use DrawClone method of the label to draw it in each of the other panels.

The option in the DrawClone method argument is the Draw option for a histogram or graph. A call to TH1::DrawClone can clone the histogram with a different draw option.

Copy/Paste Programmatically

To copy and paste the four pads from the command line or in a script you would execute the following statements:

```c
root [] .x tutorials/draw2dopt.C
root [] TCanvas cl("cl","Copy Pads",200,200,800,600);
root [] surfaces->cd(); // get the first pad
root [] TPad t1 = gPad;
root [] lego->cd(); // get the next pad
root [] TPad t2 = gPad;
root [] cont->cd(); // get the next pad
root [] TPad t3 = gPad;
root [] c2b->cd(); // get the next pad
root [] TPad t4 = gPad; // draw the four clones
root [] c1->cd();
root [] p1->DrawClone();
root [] p2->DrawClone();
root [] p3->DrawClone();
root [] p4->DrawClone();
```

Note that the pad is copied to the new canvas in the same location as in the old canvas. For example if you were to copy the third pad of surf to the top left corner of the target canvas you would have to reset the coordinates of the cloned pad.

Legends

Legends for a graph are obtained with a TLegend object. This object points to markers/lines/boxes/histories/graphics and represent their marker/line/fill attribute. Any object that has a marker or line or fill attribute may have an associated legend.

A TLegend is a panel with several entries (class TLegendEntry) and is created by the constructor

```c
TLegend( Double_t x1, Double_t y1,Double_t x2, Double_t y2,
   const char *header, Option_t *option)
```

The legend is defined with default coordinates, border size and option x1,y1,x2,y2 are the coordinates of the legend in the current pad (in NDC coordinates by default). The default text attributes for the legend are:

- Alignment = 12 left adjusted and vertically centered
- Angle = 0 (degrees)
- Color = 1 (black)
- Size = calculate when number of entries is known
- Font = helvetica-medium-r-normal scalable font = 42, and bold = 62 for title

The title It is a regular entry and supports TLatex. The default is no title (header = 0). The options are the same as for TPave; by default, they are "bNDC."

Once the legend box is created, one has to add the text with the AddEntry() method:

```c
TLegendEntry* TLegend::AddEntry(TObject *obj, const char *
   *label, Option_t *option)
```

The parameters are:

- *obj: is a pointer to an object having marker, line, or fill attributes (for example a histogram, or graph)
- label: is the label to be associated to the object
- option:
  - "L" draw line associated with line attributes of obj if obj has them (inherits from TAttLine)
  - "P" draw poly-marker associated with marker attributes of obj if obj has them (inherits from TAttMarker)
  - "F" draw a box with fill associated with fill attributes of obj if obj has them (inherits TAttFill)

One may also use the other form of AddEntry:

```c
TLegendEntry* TLegend::AddEntry(const char *name, const char *
   *label, Option_t *option)
```

Where name is the name of the object in the pad. Other parameters are as in the previous case.
Here's an example of a legend created with TLegend

```cpp
leg = new TLegend(0.4,0.6,0.89,0.89);
leg->AddEntry(fun1,"One Theory","l");
leg->AddEntry(fun3,"Another Theory","f");
leg->AddEntry(gr,"The Data","p");
leg->Draw();
// oops we forgot the blue line... add it after
leg->AddEntry(fun2, 
  "#sqrt{2#pi} P_{T} (#gamma) latex formula","f");
// and add a header (or "title") for the legend
leg->SetHeader("The Legend Title");
leg->Draw();
```

Where fun1, fun2, fun3 and gr are pre-existing functions and graphs. You can edit the TLegend by right clicking on it.

### The PostScript Interface

To generate a PostScript (or encapsulated PostScript) file for a single image in a canvas, you can:

Select the "Print PostScript" item in the canvas "File" menu. By default, a PostScript file called canvas.ps is generated.

Click in the canvas area, near the edges, with the right mouse button and select the "Print" item. You can select the name of the PostScript file. If you select canvas.ps, you will generate a PostScript file named canvas.ps. If you select canvas.eps, you will generate an encapsulated PostScript file instead.

In your program (or script), you can type:

```cpp
c1->Print("xxx.ps")
```

Or

```cpp
c1->Print("xxx.eps")
```

This will generate a file of canvas pointed to by c1.

The size of the PostScript picture, by default, is computed to keep the aspect ratio of the picture on the screen, where the size along x is always 20 cm.

You can set the size of the PostScript picture before generating the picture with a command such as:

```cpp
TPostScript myps("myfile.ps",111)
myps.Range(xsize,ysize);
object->Draw();
myps.Close();
```

The first parameter in the TPostScript constructor is the name of the file. The second parameter is the format option.

-  - ps portrait
-  - ps landscape
-  - eps

You can set the default paper size with:

```cpp
gStyle->SetPaperSize(xsize,ysize);
```

You can resume writing again in this file with myps.Open(). Note that you may have several PostScript files opened simultaneously.

To add text to a postscript file, use the method TPostScript::Text(x, y, "string"). This method writes the string in quotes into a PostScript file at position x, y in world coordinates.

### Special Characters

The following characters have a special action on the PostScript file:

- ``: Go to Greek
- ``: Go to special
- `-`: Go to Zapf Dingbats
- `?`: Go to subscript
- `^`: Go to superscript
- `!`: go to normal level of script
These special characters are printed as such on the screen. To generate one of these characters on the PostScript file, you must escape it with the escape character "@". The use of these special characters is illustrated in several scripts referenced by the TPostScript constructor.

Multiple Pictures in a PostScript File: Case 1

The following script is an example illustrating how to open a PostScript file and draw several pictures. The generation of a new PostScript page is automatic when TCanvas::Clear is called by object->Draw().

```c
{ 
    TFile f("hsimple.root");
    TCanvas c1("c1","canvas",800,600);
    //select PostScript output type
    Int_t type = 111; //portrait ps
    // Int_t type = 112;   //landscape ps
    // Int_t type = 113;   //eps
    //create a PostScript file and set the paper size
    TPostScript ps("test.ps",type);
    ps.Range(16,24);
    //set x,y of printed page
    //draw 3 histograms from file hsimple.root on separate pages
    hpx->Draw();
    c1->Update(); //force drawing in a script
    hprof->Draw();
    c1->Update();
    hpx->Draw("lego1");
    c1->Update();
    ps.Close();
}
```

Multiple Pictures a PostScript File: Case 2

This example shows 2 pages. The canvas is divided.

```c
{ 
    TFile *f1 = new TFile("hsimple.root");
    TCanvas *c1 = new TCanvas("c1");
    TPostScript *ps = new TPostScript("file.ps",112);
    c1->Divide(2,1);
    // picture 1
    ps->NewPage();
    c1->cd(1);
    hpx->Draw();
    c1->cd(2);
    hprof->Draw();
    c1->Update();
    // picture 2
    ps->NewPage();
    c1->cd(1);
    hpxpy->Draw();
    c1->cd(2);
    ntuple->Draw("px");
    ps->Close();
    // invoke PostScript viewer
    gSystem->Exec("gs file.ps");
}
```

Create or Modify a Style

All objects that can be drawn in a pad inherit from one or more attribute classes like TAttLine, TAttFill, TAttText, TAttMarker. When the objects are created, their default attributes are taken from the current style. The current style is an object of the class TStyle and can be referenced via the global variable gStyle (in TStyle.h). See the class TStyle for a complete list of the attributes that can be set in one style. ROOT provides several styles called

- "Default" The default style
- "Plain" The simple style (black and white)
- "Bold" Bolder lines
- "Video" Suitable for html output or screen viewing
The "Default" style is created by:

```c
TStyle *default = new TStyle("Default","Default Style");
```

The "Plain" style can be used if you are working on a monochrome display or if you want to get a "conventional" PostScript output. As an example, these are the instructions in the ROOT constructor to create the "Plain" style.

```c
TStyle *plain = new TStyle("Plain","Plain Style (no colors/fill areas)");
plain->SetCanvasBorderMode(0);
plain->SetPadBorderMode(0);
plain->SetPadColor(0);
plain->SetCanvasColor(0);
plain->SetTitleColor(0);
plain->SetStatColor(0);
```

You can set the current style with:

```c
gROOT->SetStyle(style_name);
```

You can get a pointer to an existing style with:

```c
TStyle *style = gROOT->GetStyle(style_name);
```

You can create additional styles with:

```c
TStyle *st1 = new TStyle("st1","my style");
st1->Set...
```

In your rootlogon.C file, you can redefine the default parameters via statements like:

```c
gStyle->SetStatX(0.7);
gStyle->SetStatW(0.2);
gStyle->SetLabelOffset(1.2);
gStyle->SetLabelFont(72);
```

Note that when an object is created, its attributes are taken from the current style. For example, you may have created a histogram in a previous session and saved it in a file. Meanwhile, if you have changed the style, the histogram will be drawn with the old attributes. You can force the current style attributes to be set when you read an object from a file by calling `gStyle->ForceStyle` before reading the objects from the file.

```c
gROOT->ForceStyle();
```

When you call `gROOT->ForceStyle()` and read an object from a ROOT file, the objects method `UseCurrentStyle()` is called. The attributes saved with the object are replaced by the current style attributes. You can also call `myObject->UseCurrentStyle()` directly. For example if you have a canvas or pad with your histogram or any other object, you can force these objects to get the attributes of the current style with:

```c
canvas->UseCurrentStyle();
```

The description of the style functions should be clear from the name of the `TStyle` setters or getters. Some functions have an extended description, in particular:

- `TStyle::SetLabelFont`
- `TStyle::SetLineStyleString`: set the format of dashed lines.
- `TStyle::SetOptStat`
- `TStyle::SetPalette` to change the colors palette
- `TStyle::SetTitleOffset`
10 Folders And Tasks

Folders

A TFolder is a collection of objects visible and expandable in the ROOT object browser. Folders have a name and a title and are identified in the folder hierarchy by an "UNIX-like" naming convention. The base of all folders is //root. It is visible at the top of the left panel in the browser. The browser shows several folders under //root.

Why Use Folders?

One reason to use folders is to reduce class dependencies and improve modularity. Each set of data has a producer class and one or many consumer classes. When using folders, the producer class places a pointer to the data into a folder, and the consumer class retrieves a reference to the folder.

The consumer can access the objects in a folder by specifying the path name of the folder.

Here is an example of a folder's path name:

//root/Event/Hits/TCP

One does not have to specify the full path name. If the partial path name is unique, it will find it, otherwise it will return the first occurrence of the path.

Creating a Folder Hierarchy

To create a folder hierarchy you add the top folder of your hierarchy to //root.

Then you add a folder to an existing folder with the TFolder::AddFolder method. This method takes two parameters: the name and title of the folder to be added. It returns a pointer of the newly created folder.

How to Use Folders

Using folders means building a hierarchy of folders, posting the reference to the data in the folder by the producer, and creating a reference to the folder by the consumer.
The code below creates the folder hierarchy shown in the browser.

```cpp
// Add the top folder of my hierarchy to //root
TFolder *aliroot = gROOT->GetRootFolder()
  ->AddFolder("aliroot", "aliroot top level folders");

// Add the hierarchy to the list of browsables
gROOT->GetListOfBrowsables() ->Add(aliroot, "aliroot");

// Create and add the constants folder
TFolder *constants = aliroot
  ->AddFolder("Constants", "Detector constants");

// Create and add the pdg folder to pdg
TFolder *pdg = constants
  ->AddFolder("DatabasePDG", "PDG database");

// Create and add the run folder
TFolder *run = aliroot
  ->AddFolder("Run", "Run dependent folders");

// Create and add the configuration folder to run
TFolder *configuration = run
  ->AddFolder("Configuration", "Run configuration");

// Create and add the run_mc folder
TFolder *run_mc = aliroot
  ->AddFolder("RunMC", "MonteCarlo run dependent folders");

// Create and add the configuration_mc folder to run_mc
TFolder *configuration_mc = run_mc
  ->AddFolder("Configuration", "MonteCarlo run configuration");
```

Posting Data to a Folder (Producer)

A TFolder can contain other folders as shown above or any TObject descendents. In general, users will not post a single object to a folder, they will store a collection or multiple collections in a folder. For example, to add an array to a folder:

```cpp
TObjArray *array;
run_mc->Add(array);
```

Reading Data from a Folder (Consumer)

One can search for a folder or an object in a folder using the TROOT::FindObjectAny method. FindObjectAny analyzes the string passed as its argument and searches in the hierarchy until it finds an object or folder matching the name.

```cpp
cnf = (TFolder*) gROOT->FindObjectAny("/aliroot/Run/Configuration");
// or
conf = (TFolder*) gROOT->FindObjectAny("Configuration");
```

A string-based search is time consuming. If the retrieved object is used frequently or inside a loop, you should save a pointer to the object as a class data member. Use the naming service only in the initialization of the consumer class.

When a folder is deleted, any reference to it in the parent or other folder is deleted also.

By default, a folder does not own the object it contains. You can overwrite that with TFolder::SetOwner. Once the folder is the owner of its contents, the contents are deleted when the folder is deleted.

Some ROOT objects are automatically added to the folder hierarchy. For example, the following folders exist on start up:

- //root/ROOT Files with the list of open Root files
- //root/Classes with the list of active classes
- //root/Geometries with active geometries
- //root/Canvases with the list of active canvases
- //root/Styles with the list of graphics styles
- //root/Colors with the list of active colors

For example, if a file myFile.root is added to the list of files, one can retrieve a pointer to the corresponding TFile object with a statement like:

```cpp
TFile *myFile = (TFile*)gROOT->FindObjectAny("/ROOT Files/myFile.root");
// or
TFile *myFile = (TFile*)gROOT->FindObjectAny("myFile.root");
```

Tasks

Tasks can be organized into a hierarchy and displayed in the browser. The TTask class is the base class from which the tasks are derived. To give a task functionality, you need to subclass the TTask class and override the Exec method.

An example of TTask subclass is in $ROOTSYS/tutorials/MyTasks.cxx.
An example script that creates a task hierarchy and adds it to the browser is $ROOTSYS/tutorials/tasks.C.
Here is part of MyTasks.cxx that shows how to subclass from TTask.

```cpp
// A set of classes deriving from TTask
// see macro tasks.C to see an example of use
// The Exec function of each class prints one
// line when it is called.
#include "TTask.h"

class MyRun : public TTask {
public:
    MyRun() {};
    MyRun(const char *name, const char *title);
    virtual ~MyRun() {};
    void Exec(Option_t *option="");

    ClassDef(MyRun,1) // Run Reconstruction task
};

class MyEvent : public TTask {
public:
    MyEvent() {};
    MyEvent(const char *name, const char *title);
    virtual ~MyEvent() {};
    void Exec(Option_t *option="");

    ClassDef(MyEvent,1) // Event Reconstruction task
};
```

Later in MyTasks.cxx, we can see examples of the constructor and overridden Exec() method:

```cpp
    - ClassImp(MyRun)
    MyRun::MyRun(const char *name, const char *title)
    : TTask(name, title) {
    }

    void MyRun::Exec(Option_t *option) {
        printf("MyRun executing\n");
    }
```

Each TTask derived class may contain other TTasks that can be executed recursively. In this way, a complex program can be dynamically built and executed by invoking the services of the top level task or one of its subtasks.

The constructor of TTask has two arguments: the name and the title. This script creates the task defined above, and creates a hierarchy of tasks.

```cpp
    // Create a hierarchy by adding sub tasks
    run->Add(geomInit);
    run->Add(matInit);
    run->Add(event);
    event->Add(tracker);
    tracker->Add(tpc);
    tracker->Add(its);
    tracker->Add(muon);
    tracker->Add(phos);
    tracker->Add(rich);
    tracker->Add(trd);
```

To execute a TTask, you call the ExecuteTask method. ExecuteTask will recursively call:

- the TTask::Exec method of the derived class
- TTask::ExecuteTasks to execute for each task the list of its subtasks.

To add the top level task
```cpp
gROOT->GetListOfTasks()->Add(run);
```

To add the task to the browser
```cpp
gROOT->GetListOfBrowsables()->Add(run);
```

Note the first line, it loads the class definitions in MyTasks.cxx with ACLiC. ACLiC builds a shared library and adds the classes to the CINT dictionary (see "How to Add a Class with ACLiC" in the chapter "Adding a Class").

If the top level task is added to the list of ROOT browse-able objects, the tree of tasks can be seen in the ROOT browser. To add it to the browser, get the list of browse-able objects first and add it to the collection.

```cpp
gROOT->GetListOfBrowsables()->Add(run);
```

The first parameter of the Add method is a pointer to a TTask, the second parameter is the string to show in the browser. If the string is left out, the name of the task is used.
After executing the script above the browser will look like this.

**Execute and Debug Tasks**

The browser can be used to start a task, set break points at the beginning of a task or when the task has completed. At a breakpoint, data structures generated by the execution up this point may be inspected asynchronously and then the execution can be resumed by selecting the "Continue" function of a task.

A Task may be active or inactive (controlled by `TTask::SetActive`). When a task is inactive, its sub tasks are not executed.

A Task tree may be made persistent, saving the status of all the tasks.
11 Input/Output

This chapter covers the saving and reading of objects to and from ROOT files. It begins with an explanation of the physical layout of a ROOT file. It includes a discussion on compression, and file recovery. Then we explain the logical file, the class TFile and its methods. We show how to navigate in a file, how to save objects and read them back. We also include a discussion on Streamers. Streamers are the methods responsible to capture an objects current state to save it to disk or send it over the network. At the end of the chapter is a discussion on the two specialized ROOT files: TNetFile and TWebFile.

The Physical Layout of ROOT Files

A ROOT file is like a UNIX file directory. It can contain directories and objects organized in an unlimited number of levels. It also is stored in machine independent format (ASCII, IEEE floating point, Big Endian byte ordering).

To look at the physical layout of a ROOT file, we first create one. This example creates a ROOT file and 15 histograms, fills each histogram with 1000 entries from a gaussian distribution, and writes them to the file.

```c
char name[10], title[20];
// Create an array of Histograms
tobjarray Hlist(0);
// create a pointer to a histogram
TH1F* h;
// make and fill 15 histograms
// and add them to the object array
for (Int_t i = 0; i < 15; i++) {
  sprintf(name,"h%d",i);
  sprintf(title,"histo nr:%d",i);
  h = new TH1F(name,title,100,-4,4);
  Hlist.Add(h);
  h->FillRandom("gaus",1000);
}
// open a file and write the array to the file
TFile f("demo.root","recreate");
Hlist->Write();
f.Close();
```

The example begins with a call to the TFile constructor. TFile is the class describing the ROOT file. In the next section, when we discuss the logical file structure, we will cover TFile in detail. You can also see that the file has the extension ".root", this convention is encouraged, however ROOT does not depend on it.

The last line of the example closed the file. To view its contents it needs to be opened again, and once opened we can view the contents in the ROOT Object browser by creating a TBrowser object.

In the browser, we can see the 15 histograms we created.

Once we have the TFile object, we can call the TFile::Map() method to view the physical layout. The output of Map() prints the date/time, the start address of the record, the number of bytes in the record, the class name of the record, and the compression factor.

```c
root [] TFile f("demo.root")
root [] TBrowser browser;
```

We see the fifteen histograms (TH1F's) with the first one starting at byte 148. We also see an entry TFile. You may notice that the first entry starts at byte 64. The first 64 bytes are taken by the file header.
The File Header
This table shows the file header information:

<table>
<thead>
<tr>
<th>Byte Value Name</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>1 -&gt; 4</td>
<td>&quot;root&quot;</td>
</tr>
<tr>
<td>5 -&gt; 8</td>
<td>fVersion</td>
</tr>
<tr>
<td>9 -&gt; 12</td>
<td>fBEGIN</td>
</tr>
<tr>
<td>13 -&gt; 16</td>
<td>fEND</td>
</tr>
<tr>
<td>17 -&gt; 20</td>
<td>fSeekFree</td>
</tr>
<tr>
<td>21 -&gt; 24</td>
<td>fNbytesFree</td>
</tr>
<tr>
<td>25 -&gt; 28</td>
<td>nfree</td>
</tr>
<tr>
<td>29 -&gt; 33</td>
<td>fName</td>
</tr>
<tr>
<td>34 -&gt; 37</td>
<td>fCompress</td>
</tr>
</tbody>
</table>

The first four bytes of the file header contain the string "root" which identifies a file as a ROOT file. Because of this identifier, ROOT is not dependent on the ".root" extension. It is still a good idea to use the extension, just for us to recognize them easier.

The nfrees value is the number of free records. A ROOT file has a maximum size of 2 gigabytes. This variable along with fNbytesFree keeps track of the free space in terms of records and bytes. This count also includes the deleted records, which are available again.

The Top Directory Description
The 84 bytes after the file header contain the top directory description, including the name, the date and time it was created, and the date and time of the last modification.

<table>
<thead>
<tr>
<th>Date</th>
<th>Time</th>
<th>N</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>20010404/092347</td>
<td>At:64</td>
<td>N=84</td>
<td>TFile</td>
</tr>
</tbody>
</table>

The Histogram Records
What follows are the 15 histograms, in records of variable length.

<table>
<thead>
<tr>
<th>Date</th>
<th>Time</th>
<th>N</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>20010404/092347</td>
<td>At:148</td>
<td>N=380</td>
<td>TH1F CX = 2.49</td>
</tr>
<tr>
<td>20010404/092347</td>
<td>At:528</td>
<td>N=377</td>
<td>TH1F CX = 2.51</td>
</tr>
</tbody>
</table>

The first four bytes of each record is an integer holding the number of bytes in this record. A negative number flags the record as deleted, and makes the space available for recycling in the next write. The rest of bytes in the header contain all the information to uniquely identify a data block on the file. This is followed by the object data.

This table explains the values in each individual record:

<table>
<thead>
<tr>
<th>Byte Value Name</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>1 -&gt; 4</td>
<td>Nbytes</td>
</tr>
<tr>
<td>5 -&gt; 6</td>
<td>Version</td>
</tr>
<tr>
<td>7 -&gt; 10</td>
<td>ObjLen</td>
</tr>
<tr>
<td>11 -&gt; 14</td>
<td>Datime</td>
</tr>
<tr>
<td>15 -&gt; 16</td>
<td>KeyLen</td>
</tr>
<tr>
<td>17 -&gt; 18</td>
<td>Cycle</td>
</tr>
<tr>
<td>19 -&gt; 22</td>
<td>SeekKey</td>
</tr>
<tr>
<td>23 -&gt; 26</td>
<td>SeekPdir</td>
</tr>
<tr>
<td>27</td>
<td>lName</td>
</tr>
<tr>
<td>28</td>
<td>ClassName</td>
</tr>
<tr>
<td>29</td>
<td>lName</td>
</tr>
<tr>
<td>30</td>
<td>Name</td>
</tr>
<tr>
<td>31</td>
<td>lTitle</td>
</tr>
<tr>
<td>32</td>
<td>Title</td>
</tr>
<tr>
<td>33</td>
<td>DATA</td>
</tr>
</tbody>
</table>

You see a reference to TKey. It is explained in detail in the next section.

The Class Description List (StreamerInfo List)
The histogram records are followed by a list of class descriptions called StreamerInfo. The list contains the description of each class that has been written to file.

<table>
<thead>
<tr>
<th>Date</th>
<th>Time</th>
<th>N</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>20010404/092347</td>
<td>At:5854</td>
<td>N=2390</td>
<td>StreamerInfo CX = 3.41</td>
</tr>
</tbody>
</table>

The class description is recursive, because to fully describe a class, its ancestors and object data members have to be described also.

In demo.root, the class description list contains the description for:

- TH1F
- all classes in the TH1F inheritance tree
- all classes of the object data members
- all classes in the object data members' inheritance tree.

This description is implemented by the TStreamerInfo class, and is often referred to as simply StreamerInfo.
You can print a file's StreamerInfo list with the TFile::ShowStreamerInfo method. Below is an example of the output. Only the first line of each class description is shown.

The demo.root example contains only TH1F objects. Here we see the recursive nature of the class description, it contains the StreamerInfo of all the classes needed to describe TH1F.

```
root [] f.ShowStreamerInfo()
StreamerInfo for class: TH1F, version=1
BASE  TH1  offset=  0 type= 1 1-Dim histogram base class

The List of Keys and The List of Free Blocks

The last three entries on the output of TFile::Map() are the list of keys, the list of free segments, and the address where the data ends. When a file is closed, it writes a linked list of keys at the end of the file. This is what we see in the second to last entry. In our example, the list of keys is stored in 732 bytes beginning at byte #244.

The second to last entry is a list of free segments. In our case, this starts 8976 and is not very long, only 53 bytes, since we have not deleted any objects.

The last entry is the address of the last byte in the file.

File Recovery

A file may become corrupted or it may be impossible to write it to disk and close it properly. For example if the file is too large and exceeds the disk quota, or the job crashes or a batch job reaches its time limit before the file can be closed. In these cases, it is imperative to recover and retain as much information as possible. ROOT provides an intelligent and elegant file recovery mechanism using the redundant directory information in the record header.

If the file is not closed due to for example exceeded the time limit, and it is opened again, it is scanned and rebuilt according to the information in the record header. The recovery algorithm reads the file and creates the saved objects in memory according to the header information. It then rebuilds the directory and file structure.

If the file is opened in write mode, the recovery makes the correction on disk when the file is closed; however if the file is opened in read mode, the correction can not be written to disk. You can also explicitly invoke the recovery procedure by calling the TFile::Recover() method.

You must be aware of the 2GB size limit before you attempt a recovery. If the file has reached this limit, you cannot add more data. You can still recover the directory structure, but you cannot save what you just recovered to the file on disk.

Here we interrupted and aborted the previous ROOT session, causing the file not to be closed. When we start a new session and attempt to open the file, it gives us an explanation and status on the recovery attempt.

```
root [] f.TFile("demo.root")
Warning in <TFile::TFile>: file demo.root probably not closed, trying to recover successfully recovered 15 keys
```

The Logical ROOT File: TFile and TKey

We saw that the TFile::Map() method reads the file sequentially and prints information about each record while scanning the file. It is not feasible to only support sequential access and hence ROOT provides random or direct access, i.e. reading a specified object at a time. To do so, TFile keeps a list of TKeys, which is essentially an index to the objects in the file. The TKey class describes the record headers of objects in the file. For example, we can get the list of keys

```
root [] f.TFile("demo.root")
```

```
20010404/09347 At: 8244 N=732    KeysList
20010404/09347 At: 8976 N=63      Freed Segments
20010404/09347 At: 9029 N=1      END
```

```

The Logical ROOT File: TFile and TKey

We saw that the TFile::Map() method reads the file sequentially and prints information about each record while scanning the file. It is not feasible to only support sequential access and hence ROOT provides random or direct access, i.e. reading a specified object at a time. To do so, TFile keeps a list of TKeys, which is essentially an index to the objects in the file. The TKey class describes the record headers of objects in the file. For example, we can get the list of keys

```
root [] f.TFile("demo.root")
```

```
20010404/09347 At: 8244 N=732    KeysList
20010404/09347 At: 8976 N=63      Freed Segments
20010404/09347 At: 9029 N=1      END
```
and print them. To find a specific object on the file we can use the

\texttt{TFile::Get()} method.

\begin{verbatim}
root [] TFile f("demo.root")
root [] f.GetListOfKeys()->Print()
TKey Name = h0, Title = histo nr:0, Cycle = 1
TKey Name = h1, Title = histo nr:1, Cycle = 1
TKey Name = h2, Title = histo nr:2, Cycle = 1
TKey Name = h3, Title = histo nr:3, Cycle = 1
TKey Name = h4, Title = histo nr:4, Cycle = 1
TKey Name = h5, Title = histo nr:5, Cycle = 1
TKey Name = h6, Title = histo nr:6, Cycle = 1
TKey Name = h7, Title = histo nr:7, Cycle = 1
TKey Name = h8, Title = histo nr:8, Cycle = 1
TKey Name = h9, Title = histo nr:9, Cycle = 1
TKey Name = h10, Title = histo nr:10, Cycle = 1
TKey Name = h11, Title = histo nr:11, Cycle = 1
TKey Name = h12, Title = histo nr:12, Cycle = 1
TKey Name = h13, Title = histo nr:13, Cycle = 1
TKey Name = h14, Title = histo nr:14, Cycle = 1
root [] TH1F *h9 = (TH1F*)f.Get("h9");
\end{verbatim}

The \texttt{TFile::Get()} finds the \texttt{TKey} object with name "h9". Using the \texttt{TKey} info it will import in memory the object in the file at the file address #3352 (see the output from the \texttt{TFile::Map} above). This is done by the Streamer method that is covered in detail in a later section.

Since the keys are available in a \texttt{TList} of \texttt{TKeys} we can iterate over the list of keys:

\begin{verbatim}
{
TFile f("demo.root");
TIter next(f.GetListOfKeys());
TKey *key;
while ((key=(TKey*)next())) {
    printf("key: %s points to an object of class: %s at %d\n", key->GetName(), key->GetClassName(), key->GetSeekKey());
}
\}
\end{verbatim}

The output of this script is:

\begin{verbatim}
root () .x iterate.C
key: h0 points to an object of class: TH1F at 150
key: h1 points to an object of class: TH1F at 503
key: h2 points to an object of class: TH1F at 854
key: h3 points to an object of class: TH1F at 1194
key: h4 points to an object of class: TH1F at 2240
key: h5 points to an object of class: TH1F at 2582
key: h6 points to an object of class: TH1F at 2937
key: h7 points to an object of class: TH1F at 3293
key: h8 points to an object of class: TH1F at 3639
key: h9 points to an object of class: TH1F at 3986
key: h10 points to an object of class: TH1F at 4339
key: h11 points to an object of class: TH1F at 4694
key: h12 points to an object of class: TH1F at 5038
\end{verbatim}

In addition to the list of keys, \texttt{TFile} also keeps two other lists:

\texttt{TFile::fFree} is a \texttt{TList} of free blocks used to recycle freed up space in the file. ROOT tries to find the best free block. If a free block matches the size of the new object to be stored, the object is written in the free block and this free block is deleted from the list. If not, the first free block bigger than the object is used.

\texttt{TFile::fListHead} contains a sorted list (\texttt{TSortedList}) of objects in memory.

The diagram below illustrates the logical view of the \texttt{TFile} and \texttt{TKey}.
Viewing the Logical File Contents

TFile is a descendent of TDirectory, which means it behaves like a TDirectory. We can list the contents, print the name, and create subdirectories. In a ROOT session, you are always in a directory and the directory you are in is called the current directory and is stored in the global variable gDirectory.

Let’s look at a more detailed example of a ROOT file and its role as the current directory. First, we create a ROOT file by executing a sample script.

```
root[] .x $ROOTSYS/tutorials/hsimple.C
```

Now you should have hsimple.root in your directory. The file was closed by the script so we have to open it again to work with it.

```
root[] TFile f("hsimple.root", "UPDATE")
```

We open the file with the intent to update it, and list its contents.

```
TFile** hsimple.root
TFile* hsimple.root
```

It shows the two lines starting with TFile followed by four lines starting with the word "KEY". The four keys tell us that there are four objects on disk in this file. The syntax of the listing is:

```
KEY: <class> <variable>;<cycle number> <title>
```

For example, the first line in the list means there is an object in the file on disk, called hpX. It is of the class TH1F (one-dimensional histogram of floating numbers). The object’s title is “This is the px distribution”.

If the line starts with OBJ, the object is in memory. The <class> is the name of the ROOT class (T-something). The <variable> is the name of the object. The cycle number along with the variable name uniquely identifies the object. The <title> is the string given in the constructor of the object as title.

This picture shows a TFile with five objects in the top directory (kObjA;1, kObjA;2, kObjB;1, kObjC;1 and kObjD;1). ObjA is on file twice with two different cycle numbers. It also shows four objects in memory (mObjE, mObjF, mObjM, mObjL). It also shows several subdirectories.

The Current Directory

When you create a TFile object, it becomes the current directory. Therefore, the last file to be opened is always the current directory. To check your current directory you can type:

```
root[] gDirectory->pwd()
```

This means that the current directory is the ROOT session (Rint). When you create a file, and repeat the command the file becomes the current directory.

```
root[] TFile f1("AFile1.root");
root[] gDirectory->pwd()
```

If you create two files, the last becomes the current directory.

```
root[] TFile f2("AFile2.root");
root[] gDirectory->pwd()
```

To switch back to the first file, or to switch to any file in general, you can use the TDirectory::cd method. The next command changes the current directory back to the first file.

```
root[] f1.cd();
root[] gDirectory->pwd()
```

Note that even if you open the file in “READ” mode, it still becomes the current directory.
CINT also offers a shortcut for `gDirectory->pwd()` and `gDirectory->ls()`, you can type:

```cpp
root [] pwd
AFile1.root:/
root [] ls
```

To return to the home directory, the one we were in before we opened any files:

```cpp
root [] gROOT->cd()
(unsigned char)1
root [] gROOT->pwd()
Rint:/
```

### Objects in Memory and Objects on Disk

The `TFile::ls()` method has an option to list the objects on disk (`-d`) or the objects in memory (`-m`). If no option is given it lists both, first the objects in memory, then the objects on disk. For example:

```cpp
root [] TFile *f = new TFile("hsimple.root");
root [] gDirectory->ls("-m")
```

Remember that `gDirectory` is the current directory and at this time is equivalent to "f". This correctly states that no objects are in memory. The next command lists the objects on disk in the current directory.

```cpp
root [] gDirectory->ls("-d")
```

To bring an object from disk into memory, we have to use it or "Get" it explicitly. When we use the object, ROOT gets it for us. Any reference to `hprof` will read it from the file. For example drawing `hprof` will read it from the file and create an object in memory. Here we draw the profile histogram, and then we list the contents:

```cpp
root [] hprof->Draw()
<TCanvas::MakeDefCanvas>: created default TCanvas with name c1
root [] f->ls()
```

We now see a new line that starts with OBJ. This means that an object of class `TProfile`, called `hprof` has been added in memory to this directory. This new `hprof` in memory is independent from the `hprof` on disk. If we make changes to the `hprof` in memory, they are not propagated to the `hprof` on disk. A new version of `hprof` will be saved once we call `Write`.

You may wonder why `hprof` is added to the objects in the current directory. `hprof` is of the class `TProfile` that inherits from `TH1D`, which inherits from `TH1`. `TH1` is the basic histogram. All histograms and trees are created in the current directory (also see "Histograms and the Current Directory"). The reference to "all histograms" includes objects of any class descending directly or indirectly from `TH1`. Hence, our `TProfile` `hprof` is created in the current directory.

There was another side effect when we called the `TH1::Draw` method. CINT printed this statement:

```cpp
<TCanvas::MakeDefCanvas>: created default TCanvas with name c1
```

It tells us that a `TCanvas` was created and it named it `c1`. This is where ROOT is being nice, and it creates a canvas for drawing the histogram if no canvas was named in the draw command, and if no active canvas exists.

The newly created canvas, however, is NOT listed in the contents of the current directory. Why is that? The canvas is not added to the current directory, because by default ONLY histograms and trees are added to the object list of the current directory. Actually, `TEventList` objects are also added to the current directory, but at this time, we don't have to worry about those.

If the canvas is not in the current directory then where is it? Because it is a `TCanvas`, it was added to the list of canvases. This list can be obtained by the command `gROOT->GetListOfCanvases()->ls()`. The `ls()` will print the contents of the list. In our list, we have one canvas called `c1`. It has a `TFrame`, a `TProfile`, and a `TPaveStats`.

```cpp
<TCanvas::MakeDefCanvas>: created default TCanvas with name c1
```

It tells us that a `TCanvas` was created and it named it `c1`. This is where ROOT is being nice, and it creates a canvas for drawing the histogram if no canvas was named in the draw command, and if no active canvas exists.

The newly created canvas, however, is NOT listed in the contents of the current directory. Why is that? The canvas is not added to the current directory, because by default ONLY histograms and trees are added to the object list of the current directory. Actually, `TEventList` objects are also added to the current directory, but at this time, we don't have to worry about those.

If the canvas is not in the current directory then where is it? Because it is a `TCanvas`, it was added to the list of canvases. This list can be obtained by the command `gROOT->GetListOfCanvases()->ls()`. The `ls()` will print the contents of the list. In our list, we have one canvas called `c1`. It has a `TFrame`, a `TProfile`, and a `TPaveStats`.

```cpp
<TCanvas::MakeDefCanvas>: created default TCanvas with name c1
```

Let's proceed with our example and draw one more histogram, and we see one more OBJ entry.
TFile::ls() loops over the list of objects in memory and the list of objects on disk. In both cases, it calls the ls() method of each object. The implementation of the ls method is specific to the class of the object, all of these objects are descendants of TObject and inherit the TObject::ls() implementation. The histogram classes are descendants of TNamed that in turn is a descent of TObject. In this case, TNamed::ls() is executed, and it prints the name of the class, and the name and title of the object.

Each directory keeps a list of its the objects in memory. You can get this list by using TDirectory::GetList. To see the lists in memory contents you can:

```cpp
root [] f->GetList()->ls()
OBJ: TProfile hprof   Profile of pz versus px : 0
OBJ: TH1F   hpx     This is the px distribution : 0
```

Since the file f is the current directory (gDirectory), this will yield the same result:

```cpp
root [] gDirectory->GetList()->ls()
OBJ: TProfile hprof   Profile of pz versus px : 0
OBJ: TH1F   hpx     This is the px distribution : 0
```

### Saving Histograms to Disk

At this time, the objects in memory (OBJ) are identical to the objects on disk (KEY). Let's change that by adding a fill to the hpx we have in memory.

```cpp
root [] hpx->Fill(0)
```

Now the hpx in memory is different from the histogram (hpx) on disk.

Only one version of the object can be in memory, however, on disk we can store multiple versions of the object. The TFile::Write method will write the list of objects in the current directory to disk. It will add a new version of hpx and hprof.

```cpp
root [] hpx->Write()
```

A call to obj->Write without any parameters will call obj->GetName() to find the name of the object and use it to create a key with the same name. You can specify a new name by giving it as a parameter to the Write method.

```cpp
root [] hpx->Write("newName")
```

If you want to re-write the same object, with the same key, use the overwrite option.
If you give a new name and use the Overwrite option, the object on disk with the matching name is overwritten if such an object exists. If not, a new object with the new name will be created.

The Write method did not affect the objects in memory at all. However, if the file is closed, the directory is emptied and the objects on the list are deleted.

This is important to remember, do not close the file until you are done with the objects or any attempt to reference the objects will fail.

When a histogram is created, it is added by default to the list of objects in the current directory. You can get the list of histograms in a directory and retrieve a pointer to a specific histogram.

You can change the directory of a histogram with the SetDirectory method.

Once a histogram is removed from the directory, it will no longer be deleted when the directory is closed. It is now your responsibility to delete this histogram object once you are finished with it.

To change the default that automatically adds the histogram to the current directory, you can call the static function:

```c
TH1::AddDirectory(kFALSE);
```

In this case, you will need to do all the bookkeeping for all the created histograms.

In addition to histograms and trees, you can save any object in a ROOT file. To save a canvas to the ROOT file you can use TDirectory::Write.

All collection classes inherit from TCollection and hence inherit the TCollection::Write method. When you call TCollection::Write() each object in the container is written individually into its own key in the file.

To write all objects into one key you can specify the name of the key and use the TObject::kSingleKey option. For example:

```c
TList * list = new TList;
TNamed * n1, * n2;
list->Add(n1);
list->Add(n2);
list->Write("list", TObject::kSingleKey);
```

A TFile object going Out of Scope

There is another important point to remember about TFile::Close and TFile::Write. When a variable is declared on the stack in a function such as in the code below, it will be deleted when it goes out of scope.

```c
void foo() {
    TFile f("AFile.root", "RECREATE");
}
```

As soon as the function foo has finished executing, the variable f is deleted. When a TFile object is deleted an implicit call to TFile::Close is made. This will save only the file descriptor to disk. It contains: the file header, the StreamerInfo list, the key list, the free segment list, and the end address.
void foo() {
    TFile f("AFile.root", "RECREATE");
    … stuff …
    f->Write();
}

To prevent an object in a function from being deleted when it goes out of scope, you can create it on the heap instead of on the stack. This will create a TFile object f, that is available on a global scope, and it will still be available when exiting the function.

void foo() {
    TFile *f = new TFile("AFile.root", "RECREATE");
}

Retrieving Objects from Disk

If you have a ROOT session running, please quit and start fresh.

We saw that multiple versions of an object with the same name can be in a ROOT file. In our example, we saved a modified histogram hpx to the file, which resulted in two hpx's uniquely identified by the cycle number: hpx;1 and hpx;2. The question is how do we retrieve the right version of hpx.

When opening the file and using hpx, CINT retrieves the one with the highest cycle number.

To read the hpx;1 into memory, rather than the hpx;2 we would get by default, we have to explicitly get it and assign it to a variable.

root [] TFile *f1 = new TFile("hsimple.root")
root [] TH1F *hpx1 = (TH1F*) f1->Get("hpx;1")

Subdirectories and Navigation

The TDirectory class lets you organize its contents into subdirectories, and TFile being a descendant of TDirectory inherits this ability.

Here is an example of a ROOT file with multiple subdirectories as seen in the ROOT browser.

Creating Subdirectories

To add a subdirectory to a file use Directory::mkdir.
When retrieving an object from a subdirectory, you can navigate to the subdirectory first or give it the path name relative to the file. The read object is created in memory in the current directory.

In this first example, we get `histo` from the top directory and the object will be in the top directory.

```
root [] f->Write()
root [] gDirectory->ls()
TDirectory* Wed011003 Wed011003
OBJ: TH1F histo histo : 0
KEY: TH1F histo;1 histo
```

When retrieving an object from a subdirectory, you can navigate to the subdirectory first or give it the path name relative to the file. The read object is created in memory in the current directory.

In this example, we get `histo` from the top directory and the object will be in the top directory.

```
root [] TH1 *h = (TH1*) f->Get("Wed011003/histo;1")
```

If file is written, a copy of `histo` will be in the top directory. This is an effective way to copy an object from one directory to another.

In contrast, in the code box below, `histo` will be in memory in the subdirectory because we changed the current directory.

```
root [] f->cd("Wed011003");
root [] TH1 *h = (TH1*) gDirectory->Get("histo;1")
```

Note that there is no warning if the retrieving was not successful. You need to explicitly check the value of `h`, and if it is null, the object could not be found. For example, if you did not give the path name the histogram cannot be found and the pointer to `h` is null.

```
root [] TH1 *h = (TH1*) gDirectory->Get("Wed011003/histo;1")
root [] h (class TH1*)0x10767de0
root [] TH1 *h = (TH1*) gDirectory->Get("histo;1")
root [] h (class TH1*)0x0
```

Removing Subdirectories

To remove a subdirectory you need to use `TDirectory::Delete`. There is no `TDirectory::rmdir`. The `Delete` method takes a string containing the variable name and cycle number as a parameter.

```
void Delete(const char *namecycle)
```

The `namecycle` string has the format `name;cycle`. Here are some rules to remember:

- name = * means all, but don't remove the subdirectories
- cycle = * means all cycles (memory and file)
- cycle = means apply to a memory object
- cycle = 9999 also means apply to a memory object
- namecycle = * means the same as namecycle = T
- namecycle = T delete subdirectories

For example to delete a directory from a file, you must specify the directory cycle.

```
root [] f->Delete("Wed011003;1")
```

Some other examples of namecycle format are:

- foo: delete the object named `foo` from memory
- foo;1 delete the cycle 1 of the object named `foo` from the file
- foo;* delete all cycles of `foo` from the file and also from memory
- *;2 delete all objects with cycle number 2 from the file
- *;* delete all objects from memory and from the file including all subdirectories

Streamers

To follow the discussion on Streamers, you need to know what a simple data type is. A variable is of a simple data type if it cannot be decomposed into other types. Examples of simple data types are longs, shorts, floats, and chars. In contrast, a variable is of a composite data type if it can be decomposed. For example, classes, structures, and arrays are composite types. Simple types are also called primitive types, basic types, and CINT sometimes calls them fundamental types.

When we say, "writing an object to a file", we actually mean writing the current values of the data members. The most common way to do this is to decompose (also called the serialization of) the object into its data members and write them to disk. The decomposition is the job of the Streamer. Every class with ambitions to be stored in a file has a Streamer that decomposes it and "streams" its members into a buffer.

The methods of the class are not written to the file, it contains only the persistent data members.

To decompose the parent classes, the Streamer calls the Streamer of the parent classes. It moves up the inheritance tree until it reaches an ancestor without a parent.

To serialize the object data members it calls their Streamer. They in turn move up their own inheritance tree and so forth.

The simple data members are written to the buffer directly. Eventually the buffer contains all simple data members of all the classes that make up this particular object.

Streaming Pointers

An object pointer data member presents a challenge to the streaming software. If the object pointed to is saved every time it could create circular dependencies and consume large amounts of disk space. The network of references must be preserved on disk and recreated upon reading the file.

When ROOT encounters a pointer data member it calls the streamer of the object and labels it with a unique object identifier. The object identifier is unique for one I/O operation. If there is another reference to the object in the same I/O operation, the first object only referenced by its ID, it is not saved again.
When reading the file, the object is rebuilt and the references recalculated. In this way, the network of pointers and their objects is rebuilt and ready to use the same way it was used before it was persistent.

Automatically Generated Streamers

A Streamer usually calls other Streamers: the Streamer of its parents and data members. This architecture depends on all classes having Streamers, because eventually they will be called. To ensure that a class has a Streamer, rootcint automatically creates one in the ClassDef macro which is defined in $ROOTSYS/include/Rtypes.h. ClassDef defines several methods for any class, and one of them is the Streamer. The automatically generated Streamer is complete and can be used as long as no customization is needed.

The Event class is defined in $ROOTSYS/test/Event.h. Looking at the class definition, we find that it inherits from TObject. It is a simple example of a class with diverse data members.

```
class Event : public TObject {
  private:
    TDirectory    *fTransient;    // current directory
    Float_t  fPt;              // transient value
    char           fType[20];
    Int_t          fNtrack;
    Int_t          fNseg;
    Int_t          fNtrack;
    Int_t          fNvertex;
    UInt_t         fFlag;
    Float_t        fTemperature;
    EventHeader    fEvtHdr;
    TClonesArray  *fTracks;
    TH1F          *fH;
    Int_t          fMeasures[10];
    Float_t        fMatrix[4][4];
    Float_t       *fClosestDistance;  // || don't split

  void Event::Streamer(TBuffer &R__b)
  { // Stream an object of class Event.
    if (R__b.IsReading()) {
      Event::Class()->ReadBuffer(R__b, this);
    } else {
      Event::Class()->WriteBuffer(R__b, this);
    }
  }
```

Transient Data Members (!)

To prevent a data member from being written to the file, insert a "!" as the first character after the comment marks. For example, in this version of Event, the fPt and fTransient data members are not persistent.

```
class Event : public TObject {
  private:
    TDirectory    *fTransient;    // current directory
    Float_t  fPt;              // transient value
    char           fType[20];
    Int_t          fNtrack;
    Int_t          fNseg;
    Int_t          fNvertex;
    UInt_t         fFlag;
    Float_t        fTemperature;
    EventHeader    fEvtHdr;
    TClonesArray  *fTracks;
    TH1F          *fH;
    Int_t          fMeasures[10];
    Float_t        fMatrix[4][4];
    Float_t       *fClosestDistance;  // || don't split
```
For example:

```cpp
class Event : public TObject {
private:
  char           fType[20];
  Int_t          fNtrack;
  Int_t          fNseg;
  Int_t          fNvertex;
  ...
  Float_t       *fClosestDistance; //fNvertex
  ...
}
```

The array `fClosestDistance` is defined as a pointer of floating point numbers. A comment mark (`//`), and the number in square brackets tell the Streamer the length of the array for this object. In general the syntax is:

```
<simple type>  *<name>  //<length>
```

The length cannot be an expression. If a variable is used, it needs to be an integer data member of the class. It must be defined ahead of its use, or in a base class.

**Prevent Splitting (///)**

If you want to prevent a data member from being split when writing it to a tree append the characters `///` right after the comment string. This only makes sense for object data members. For example:

```cpp
EventHeader    fEvtHdr; //|| do not split the header
```

### Streamers With Special Additions

Most of the time you can let `rootcint` generate a Streamer for you. However if you want to write your own Streamer you can do so.

For some classes, it may be necessary to execute some code before or after the read or write block in the automatic Streamer. For example after the execution of the read block, one can initialize some non persistent members.

There are two reasons why you would need to write your own Streamer. If you have a complex STL container type data member that is not yet supported by ROOT, or if you have a non-persistent data member that you want to initialize to a value depending on the read data members. In addition, the automatic Streamer does not support C-structures. It is best to convert the structure to a class definition.

First, you need to tell `rootcint` not to build a Streamer for you. The input to the `rootcint` command (in the makefile) is a list of classes in a `LinkDef.h` file. For example, the list of classes for `Event` are listed in `$ROOTSYS/test/EventLinkDef.h`. The `*` at the end of the class name tells `rootcint` not to generate a Streamer. In the example, you can see the `Event` class is the only one for which `rootcint` is instructed not to generate a Streamer.

```cpp
#define __CINT__

#pragma link off all globals;
#pragma link off all classes;
#pragma link C++ class EventHeader+;
#pragma link C++ class Event-;
#pragma link C++ class HistogramManager+;
#pragma link C++ class Track+;
#endif
#pragma link C++ class EventHeader
```

The `*` sign tells `rootcint` to use the new Streamer system introduced in ROOT 3.0.

This is an example of a customized Streamer for `Event`:

The Streamer takes a `TBuffer` as a parameter, and first checks to see if this is a case of reading or writing the buffer.

```cpp
void Event::Streamer(TBuffer &R__b) {
  if (R__b.IsReading()) {
    Event::Class()->ReadBuffer(R__b, this);
    fTransient = gDirectory;  //save current directory
    fPt= TMath::Sqrt(fPx*fPx + fPy*fPy + fPz*fPz);
  } else {
    Event::Class()->WriteBuffer(R__b, this);
  }
}
```

### Writing Objects

The Streamer decomposes the objects into data members and writes them to a buffer. It does not write the buffer to a file, it simply populates a buffer with bytes representing the object. This allows us to write the buffer to a file or do anything else we could do with the buffer. sprawling the buffer to a string, or writing it to a socket to send it over the network. This is beyond the scope of this chapter, but it is worthwhile to emphasize the need and advantage of separating the creation of the buffer from its use. Let's look how a buffer is written to a file.

A class needs to inherit from `TObject` or use `TDirectory->Write(obj)` to be saved to disk. However, a class that is a data member of another class does not have to inherit from `TObject`. It only has to have a Streamer. `EventHeader` is an example of such a case.

The `TObject::Write` method does the following:

1. Creates a `TKey` object in the current directory
2. Creates a `TBuffer` object which is part of the newly created `TKey`
3. Fills the `TBuffer` with a call to the class::Streamer method
4. Creates a second buffer for compression, if needed
5. Reserves space by scanning the `TFree` list. At this point, the size of the buffer is known.
6. Writes the buffer to the file
7. Releases the `TBuffer` part of the key
In other words, the TObject::Write calls the Streamer method of the class to build the buffer. The buffer is in the key and the key is written to disk. Once written to disk the memory consumed by the buffer part is released. The key part of the TKey is kept. The key consumes about 60 bytes, where the buffer since it contains the object data can be very large.

This is a diagram of a streamed TH1F in the buffer:

Ignore Object Streamers

You can instruct your class to ignore the TObject Streamer with the MyClass::Class::IgnoreTObjectStreamer method. When the class kIgnoreTObjectStreamer bit is set (by calling the IgnoreTObjectStreamer method), the automatically generated Streamer will not call TObject::Streamer, and the TObject part of the class is not streamed to the file. This is useful in case you do not use the TObject fBits and fUniqueID data members. You gain space on the file, and you do not lose functionality if you do not use the fBits and fUniqueID (see the section on TObject on the use of fBits and fUniqueID).

Streaming a TClonesArray

When writing a TClonesArray it bypasses by default the Streamer of the member class and uses a more efficient internal mechanism to write the members to the file.

You can override the default and specify that the member class Streamer is used by setting the TClonesArray::BypassStreamer bit to false:

```cpp
TClonesArray *fTracks;
fTracks->BypassStreamer(kFALSE); // use the member Streamer
```

When the kBypassStreamer bit is set, the automatically generated Streamer can call TClass::WriteBuffer directly. Bypassing the Streamer improves the performance when writing/reading the objects in the TClonesArray. However, the drawback is: when a TClonesArray is written with split=0 bypassing the Streamer, the StreamerInfo of the class in the array being optimized, one cannot later use the TClonesArray with split>0.

For example, there is a problem with the following scenario:

1- a class Foo has a TClonesArray of Bar objects

2- the Foo object is written with split=0 to Tree T1. In this case the StreamerInfo for the class Bar is created in optimized mode by such a way that data members of the same type are written as an array improving the I/O performance.

3- in a new program, T1 is read and a new Tree T2 is created with the object Foo in split=1.

When the T2 branch is created, the StreamerInfo for the class Bar is created with no optimization (mandatory for the split mode). The optimized Bar StreamerInfo is going to be used to read the TClonesArray in T1. The result will be Bar objects with data member values not in the right sequence. The solution to this problem is to call BypassStreamer(kFALSE) for the TClonesArray. In this case, the normal Bar::Streamer function will be called. The BAR::Streamer function works OK independently if the Bar StreamerInfo had been generated in optimized mode or not.

Pointers and References in Persistency

An object pointer data member presents a challenge to the streaming software. If the object pointed to is saved every time, it could create circular dependencies and consume a large amount of disk space. The network of references must be preserved on disk and recreated upon reading the file.

If you use independent I/O operations for pointers and their referenced object you can use the TRef class. Later in this section is an example that compares disk space, memory usage, and I/O times of C++ pointers and TRefs. In general, a TRef is faster than C++ but the advantage of a C++ pointer is that it is already C++.

Streaming C++ Pointers

When ROOT encounters a pointer data member it calls the Streamer of the object and labels it with a unique object identifier. The object identifier is unique for one I/O operation. If there is another pointer to the object in the same I/O operation, the first object is referenced i.e. it is not saved again.

When reading the file, the object is rebuilt and the references recalculated. In this way, the network of pointers and their objects is rebuilt and ready to use the same way it was used before it was persistent.
write the referenced objects, and multiple copies will exist. In addition, if the
pointer is read before the referenced object, it is null and may cause a run time
system error.

To address these limitations, ROOT offers the TRef class. TRef allows
referring an object in a different branch and/or in a different file. TRef also
supports the complex situation where a TFile is updated multiple times on the
same machine or a different machine.

When a TRef is read before its referenced object, it is null. As soon as the
referenced object is read, the TRef points to it. In addition, one can specify an
action to be taken by TRef in the case it is read before its reference object (see
Action on Demand below).

Using TRef

A TRef is a lightweight object pointing to any TObject. This object can be used
instead of normal C++ pointers in case

• The referenced object R and the pointer P are not written to the same file
• P is read before R
• R and P are written to different Tree branches

Below is a line from the example in $ROOTSYS/test/Event.cxx.

```cpp
TRef fLastTrack;      // pointer to last track
TRef P;              // to set the pointer
```

The track and its reference fLastTrack can be written with two separate i/o calls
in the same or in different files, in the same or in different branches of a
TTree.

If the TRef is read and the referenced object has not yet been read, TRef will
return a null pointer. As soon as the referenced object will be read, TRef will
point to it.

How does it work?

A TRef is itself a TObject with an additional transient pointer fPID. When a
TRef is used to point to a TObject *R.

For example in a class with

```cpp
TRef P;
```

one can do:

```cpp
P = R; // to set the pointer
```

When the statement P = R is executed, the following happens:

• The pointer fPID is set to the current TProcessID (see below).
• The current ObjectNumber (see below) is incremented by one.
• R.fUniqueID is set to ObjectNumber.
• In the fPID object, the element fObjects[ObjectNumber] is set to P
• P.fUniqueID is also set to ObjectNumber.

After having set P, one can immediately return the value of R using

```cpp
P.GetObject;().
```

This function returns the fObjects[fUniqueID] from the fPID object.

When the TRef is written, the process id number pidf of fPID is written in
addition to the TObject part of TRef (fBits, fUniqueID).

When the TRef is read, its pointer fPID is set to the value stored in the
TObject of TFile::fProcessIDs (fProcessIDs[pidf]).

When a referenced object is written, TObject::Streamer writes the pidf in
addition to the standard fBits and fUniqueID.

When TObject::Streamer reads a reference object, the pidf is read. At this
point, the referenced object is entered into the table of objects of the
TProcessID corresponding to pidf.

WARNING: If MyClass is the class of the referenced object, The TObject part
of MyClass must be streamed. One should not call

```cpp
MyClass::Class() -> IgnoreTObjectStreamer();
```

TProcessID and TUUID

A TProcessID uniquely identifies a ROOT job. The TProcessID file consists of
a UUID object, which provides a globally unique identifier.

The UUID class implements the UUID (Universally Unique Identifier), also
known as GUID (Globally Unique Identifier). A UUID is 128 bits long, and if
generated according to this algorithm, is either guaranteed to be different from all
other UUID generated until 3400 A.D. or extremely likely to be different.

The TROOT constructor automatically creates a TProcessID. When a TFile
contains referenced objects, the TProcessID object is written to the file. If a file
has been written in multiple sessions (same machine or not), a TProcessID is
written for each session. The TProcessID objects are used by TRef to uniquely
identify the referenced TObject.

When a referenced object is read from a file (its blk1sReferenced is set), this
object is entered into the objects table of the corresponding TProcessID. Each
TFile has a list of TProcessIDs (see TFile::fProcessIDs) also accessible
via TProcessID::fgPIDs (for all files).

When this object is deleted, it is removed from the table via the cleanup
mechanism invoked by the TObject destructor.

Each TProcessID has a table (TObject *fObjects) that keeps track of all
referenced objects. If a referenced object has a fUniqueID, a pointer to this
unique object may be found via fObjects->At (fUniqueID). In the same
way, when a TRef::GetObject is called, GetObject uses its own
fUniqueID to find the pointer to the referenced object. See

```cpp
TProcessID::GetObjectWithID and PutObjectWithID.
```

ObjectNumber

When an object is referenced, a unique identifier is computed and stored in both
the fUniqueID of the referenced and referencing object. This uniqueID is
computed by incrementing by one the static global TProcessID::fgNumber.

fUniqueID is some sort of serial object number in the current session. One can
retrieve at any time the current value of fgNumber by calling the static function
TProcessID::GetObjectCount or set this number via

```cpp
TProcessID::SetObjectCount.
```

To avoid growing a table of TObject’s in TProcessID, in case, for example, one processes many events in a loop, it
might be necessary to reset the ObjectNumber at the end of processing of one event. See an example in $ROOTSYS/test/Event.cxx (look at function Build).

The value of ObjectNumber may be saved at the beginning of one event and reset to this original value at the end of the event. These actions may be nested.

```
saveNumber = TProcessID::GetObjectCount();
TProcessID::SetObjectCount(savedNumber);
```

**Action on Demand**

The normal behavior of a TRef has been described above. In addition, TRef supports "Actions on Demand". It may happen that the object referenced is not yet in memory, on a separate file or not yet computed. In this case, TRef is able to automatically execute an action:

- Call to a compiled function (static function of member function)
- Call to an interpreted function
- Execution of a CINT script

**How to select this option?**

In the definition of the TRef data member in the original class, do:

```
TRef fRef; //EXEC:execName points to something
```

When the special keyword "EXEC:" is found in the comment field of the member, the next string is assumed to be the name of a TExec object. When a file is connected, the dictionary of the classes on the file is read in memory (see TFile::ReadStreamerInfo). When the TStreamerElement object is read, a TExec object is automatically created with the name specified after the keyword "EXEC:" in case a TExec with a same name does not already exist.

The action to be executed via this TExec can be specified with:

- A call to the TExec constructor, if the constructor is called before
- Opening the file.
- A call to TExec::SetAction at any time.

One can compute a pointer to an existing TExec with a name with:

```
TExec *myExec = gROOT->GetExec(execName);
myExec->SetAction(actionCommand);
```

actionCommand is a string containing a CINT instruction.

Examples:

```
myExec->SetAction("LoadHits()");
myExec->SetAction(".x script.C");
```

When a TRef is de-referenced via TRef::GetObject, its TExec is automatically executed. The TExec function/script can do one or more of the following:

- Load a file containing the referenced object. This function typically looks in the file catalog (GRID).
- Compute a pointer to the referenced object and communicate this pointer back to the calling function TRef::GetObject via:

```
TRef::SetObject(object).
```

As soon as an object is returned to GetObject, the fUniqueID of the TRef is set to the fUniqueID of the referenced object. At the next call to GetObject, the pointer stored in fPid fObjects[fUniqueID] will be returned directly.

An example of action on demand is in $ROOTSYS/test/Event.h:

```
TRef fWebHistogram; //EXEC:GetWebHistogram
```

When calling fWebHistogram.GetObject(), the function GetObject will automatically invoke the script GetWebHistogram.C via the interpreter. An example of a GetWebHistogram.C script is shown below:

```
void GetWebHistogram() {
  TFile *f=TFile::Open("http://root.cern.ch/files/pippa.root");
  f->cd("DM/CJ");
  TH1 *h6 = (TH1*)gDirectory->Get("h6");
  h6->SetDirectory(0);
  delete f;
  TRef::SetObject(h6);
}
```

In the above example, a call to fWebHistogram.GetObject() executes the script with the function GetWebHistogram. This script connects a file with histograms: pippa.root on the ROOT Web site and returns the object h6 to TRef::GetObject.

Note that if the definition of the TRef fWebHistogram had been:

```
TRef fWebHistogram; //EXEC:GetWebHistogram()
```

The compiled or interpreted function GetWebHistogram() would have been called instead of the CINT script GetWebHistogram.C.

**Array of TRef**

When storing multiple TRef’s, it is more efficient to use a TRefArray. The efficiency is due to having a single pointer fPid for all TRef in the array. It has a dynamic compact table of fUniqueIDs. We recommend that you use a TRefArray rather than a collection of TRefs.

Example:

- Suppose a TObjArray *mytracks containing a list of Track objects.
- Suppose a TRefArray *pions containing pointers to the pion tracks in mytracks. This list is created with statements like: pions->Add(track);
- Suppose a TRefArray *muons containing pointers to the muon tracks in mytracks.

The 3 arrays mytracks, pions and muons may be written separately.
Schema Evolution

Schema evolution is a problem faced by long-lived data. When a schema changes, existing persistent data can become inaccessible unless the system provides a mechanism to access data created with previous versions of the schema.

In the lifetime of a collaboration, the class definitions (i.e. the schema) are likely to change frequently. Not only can the class itself change, but any of its parent classes or data member classes can change also. This makes the support for schema evolution necessary.

ROOT fully supports schema evolution. The diagram below illustrates some of the scenarios.

The top half represents different versions of the shared library with the class definitions. These are the in-memory class versions.

The bottom half represents data files that contain different versions of the classes.

1) An old version of a shared library and a file with new class definitions. This can be the case when someone has not updated the library and is reading a new file.
2) Reading a file with a shared library that is missing a class definition (i.e. missing class D).
3) Reading a file without any class definitions. This can be the case where the class definition is lost, or unavailable.
4) The current version of a shared library and an old file with old class versions (backward compatibility). This is often the case when reading old data.
5) Reading a file with a shared library built with MakeProject. This is the case when someone has already read the data without a shared library and has used ROOT’s MakeProject feature to reconstruct the class definitions and shared library (MakeProject is explained in detail later on).

In case of a mismatch between the in-memory version and the persistent version of a class, ROOT maps the persistent one to the one in memory. This allows you to change the class definition at will, for example:

1) Change the order of data members in the class.
2) Add new data members. By default the value of the missing member will be 0 or in case of an object it will be set to null.
3) Remove data members.
4) Move a data member to a base class or vice versa.
5) Change the type of a member if it is a simple type or a pointer to a simple type. If a loss of precision occurs, a warning is given.
6) Add or remove a base class

ROOT supports schema evolution by keeping a class description of each version of the class that was ever written to disk, with the class. When it writes an object to file, it also writes the description of the current class version along with it. This description is implemented in the StreamerInfo class.

The StreamerInfo Class

Each class has a list of StreamerInfo objects, one for each version of the class if that version was written to disk at least once. When reading an object from a file, the system uses the StreamerInfo list to decode an object into the current version.

The StreamerInfo is made up of StreamerInfoElements. Each describes one persistent data member of the class.

By default all data members of a class are persistent. To exclude a data member (i.e. make it not persistent), add a “!” after the comment marks.
BASE          TNamed        offset=  0 type=67 The basis for a named object
BASE          TAttLine      offset= 28 type= 0 Line attributes
BASE          TAttFill      offset= 40 type= 0 Fill area attributes
BASE          TAttMarker     offset= 48 type= 0 Marker attributes
Int_t        fNumber        offset= 64 type= 2 number of bins
fBarOffset    offset=448     type= 2 (1000*offset) for bar charts or legos
Short_t       fBarWidth      offset=450     type= 2 (1000*width) for bar charts or legos
Stat_t        fNormFactor    offset=504     type= 8 Normalization factor
Stat_t        fTsumwx2       offset=508     type= 8 Total Sum of weight*X*X
Stat_t        fTsumw2        offset=512     type= 8 Total Sum of squares of weights
Stat_t        fTsumw         offset=516     type= 8 Total Sum of weights
Double_t      fMaximum       offset=520     type= 8 Maximum value for plotting
Double_t      fMinimum       offset=524     type= 8 Minimum value for plotting
Double_t      fConv          offset=528     type= 8 Normalization factor
TArrayD       fContour       offset=540     type= 8 Array to display contour levels
TArrayD       fSumw2        offset=544     type= 8 Array of sum of squares of weights
TArrayD       fSumw          offset=548     type= 8 Total Sum of squares of weights
TAttLine      offset=13      type= 0 Line attributes
fFunctions    offset=548     type= 1 Pointer to list of functions
fOption       offset=560     type= 1 Histogram options
fPainter      offset=576     type= 1 Pointer to histogram painter

The StreamerInfoElement Class
A StreamerInfoElement describes a data member of a simple type, object, array, pointer, or container.

The offset in the StreamerInfoElement is the starting address of the data for that data member.

BASE          TNamed        offset=  0 type=67 The basis for a named object
BASE          TAttLine      offset= 28 type= 0 Line attributes

Example: TH1 StreamerInfo
In the StreamerInfo of the TH1 class we see the four base classes: TNamed, TAttLine, TAttFill, and TAttMarker. These are followed by a list of the data members. Each data member is implemented by a StreamerInfoElement.
Manual Schema Evolution

If you have written your own Streamer as described in the section "Streamers With Special Additions", you will have to manually add code for each version and manage the evolution of your class. When you add or remove data members, you must modify the Streamer by hand. ROOT assumes that you have increased the class version number in the ClassDef statement and introduced the relevant test in the read part of the Streamer.

For example, if a new version of the Event class above includes a new member:

```
Int_t m_Hits
```

the ClassDef(Event, 2) and the following lines should be added to the read part of the Streamer:

```
if (R__v > 1) {
    B_i = Nth;
} else {
    fNew = 0;  // set to some default value
}
```

Once we compile and run ATLFast we get a ROOT file called atlfast.root, containing the ATLFast objects.

Building Class Definitions With The StreamerInfo

A ROOT file's StreamerInfo list contains the description of all versions of all classes in the file. When a file is opened the StreamerInfo is read into memory and it provides enough information to make the file browsable.

The StreamerInfo enables us to recreate a header file for the class in case the compiled class is not available. This is done with the TFile::MakeProject method. It creates a directory with the header files for the named classes and a makefile to compile a shared library with the class definitions.

```
// The fake class has a StreamerInfo
root[] gROOT->GetClass("ATLFMuon")
(const class TClass*)0x87e5c08

StreamerInfo for class: ATLFMuon, version:1
BASE TObject offset: 0 type:66 Basic ROOT object
BASE ATLFast offset: 0 type:67 Basic ROOT object
Int_t m_Hits offset: 0 type: Int_t
Int_t m_Eta offset: 0 type: Int_t
Int_t m_Phi offset: 0 type: Int_t
Int_t m_PT offset: 0 type: Int_t
```

However, when we try to use a specific class, we get a warning because the class is not in the CINT dictionary.

We can create a Class using gROOT->GetClass, which makes a fake class from the StreamerInfo.

```
root[] f.ShowStreamerInfo()
```

// Build a 'fake' class
root[] gROOT->GetClass("ATLFMuon")
(const class TClass*)0x87e5c08

StreamerInfo for class: ATLFMuon, version:1
BASE TObject offset: 0 type:66 Basic ROOT object
BASE TObjArray offset: 0 type:67 Basic ROOT object
Int_t m_Hits offset: 0 type: Int_t
Int_t m_Eta offset: 0 type: Int_t
Int_t m_Phi offset: 0 type: Int_t
Int_t m_PT offset: 0 type: Int_t

```
// The fake class has a StreamerInfo
root[] gROOT->GetClass("ATLFMuon")->GetStreamerInfo()->xs() (const class TClass*)0x87e5c08
```

```
StreamerInfo for class: ATLFMuon, version:1
BASE TObject offset: 0 type:66 Basic ROOT object
BASE TObjArray offset: 0 type:67 Basic ROOT object
Int_t m_Hits offset: 0 type: Int_t
Int_t m_Eta offset: 0 type: Int_t
Int_t m_Phi offset: 0 type: Int_t
Int_t m_PT offset: 0 type: Int_t
```

Example: MakeProject

To explain the details, we use the example of the ATLFast project which is a fast simulation for the ATLAS experiment. The complete source for ATLFast can be downloaded at: ftp://root.cern.ch/root/atlfast.tar.gz.

Once we compile and run ATLFast we get a ROOT file called atlfast.root, containing the ATLFast objects.

```
if (R__v > 1) {
    B_i = Nth;
} else {
    fNew = 0;  // set to some default value
}
```

Our experience with manual schema evolution shows that it is easy to make and mismatches between Streamer writers and readers are frequent and increase as the number of classes increases.

We recommend you use rootcint generated Streamers whenever you can, and profit from the automatic schema evolution.

When we open the file, we get a warning that the file contains classes that are not in the CINT dictionary. This is correct since we did not load the class definitions.

```
Warning in <TClass::TClass>: no dictionary for class ATLFMuon is available
Warning in <TClass::TClass>: no dictionary for class TMCParticle is available
```

When we open the file, we get a warning that the file contains classes that are not in the CINT dictionary. This is correct since we did not load the class definitions.

```
Warning in <TClass::TClass>: no dictionary for class ATLFMuon is available
Warning in <TClass::TClass>: no dictionary for class TMCParticle is available
```

The StreamerInfo enables us to recreate a header file for the class in case the compiled class is not available. This is done with the TFile::MakeProject method. It creates a directory with the header files for the named classes and a makefile to compile a shared library with the class definitions.

```
// Build a 'fake' class
root[] gROOT->GetClass("ATLFMuon")
(const class TClass*)0x87e5c08

StreamerInfo for class: ATLFMuon, version:1
BASE TObject offset: 0 type:66 Basic ROOT object
BASE ATLFast offset: 0 type:67 Basic ROOT object
Int_t m_Hits offset: 0 type: Int_t
Int_t m_Eta offset: 0 type: Int_t
Int_t m_Phi offset: 0 type: Int_t
Int_t m_PT offset: 0 type: Int_t
```

```
// The fake class has a StreamerInfo
root[] gROOT->GetClass("ATLFMuon")->GetStreamerInfo()->xs() (const class TClass*)0x87e5c08
```

```
StreamerInfo for class: ATLFMuon, version:1
BASE TObject offset: 0 type:66 Basic ROOT object
BASE TObjArray offset: 0 type:67 Basic ROOT object
Int_t m_Hits offset: 0 type: Int_t
Int_t m_Eta offset: 0 type: Int_t
Int_t m_Phi offset: 0 type: Int_t
Int_t m_PT offset: 0 type: Int_t
```

```
// Build a 'fake' class
root[] gROOT->GetClass("ATLFMuon")

```

MakeProject has three parameters:

```
MakeProject(const char *dirname, const char *classes, Option_t *option)
```

The first is the directory name in which to place the generated header files. The second parameter is the name of the classes to include in the project. By default all classes are included. It recognizes the wild card character "." for example: "ATLF\t" includes all classes beginning with ATL.
The third parameter is an option with the following values:

- "new": If the directory does not exist, it is created.
- "recreate": If the directory does not exist, it is created as in "new", in addition if the directory does exist, all existing files are deleted before creating the new files.
- "update": The new classes are added to the existing directory and the existing classes are replaced with the new definition. If the directory does not exist, it creates it as in "new".
- "+": This option can be used in combination with the other three. It will create the necessary files to easily build a shared library containing the class definitions. Specifically it will:
  - Generate a script called make that builds the shared library containing the definition of all classes in the directory.
  - Generate a LinkDef.h files to use with rootcint in make.
  - Run rootcint to generate a <dirname>ProjectDict.cxx file.
  - Compile the <dirname>ProjectDict.cxx with the current options in compiledata.h.
  - Build a shared library <dirname>.so.
- "++": This option can be used instead of the single "+". It does everything the single "+" does, and dynamically loads the shared library <dirname>.so.

This example makes a directory called MyProject that will contain all class definition from the atlfast.root file. The necessary makefile to build a shared library are also created, and since the "++" is appended, the shared library is also loaded.

```
root [] f.MakeProject("MyProject","*", "recreate++")
MakeProject has generated 0 classes in MyProject
MyProject/MAKE file has been generated
Shared lib MyProject/MyProject.so has been generated
Shared lib MyProject/MyProject.so has been dynamically linked
```

The contents of MyProject:

```
ATLFCluster.h  ATLJJet.h  ATLFMiscMaker.h
ATLFTrack.h     MAKE      TMCParticle.h
ATLFClusterMaker.h  ATLJJetMaker.h  ATLFMuon.h
ATLFTrackMaker.h  MyProject.so
ATLFElectron.h   ATLFMCMaker.h  ATLFMuonMaker.h
ATLFFTrigger.h   MyProjectProjectDict.cxx
ATLFFElectronMaker.h  ATLFFMuon.h
ATLFFTriggerMaker.h  MyProjectProjectDict.h
ATLFHistBrowser.h  ATLFMisc.h  ATLFPhotonMaker.h
LinkDef.h      MyProjectProjectDict.o
```

Now you can load the shared library in any consecutive root session to use the atlfast classes.

```
root [] gSystem->Load("*MyProject*/MyProject")
root [] ATLFMuon muon
```

This is an example of a generated header file:

```
/////////////////////////////////////////////////////////
//   This class has been generated by TFile::MakeProject
//     (Thu Apr  5 10:18:37 2001 by ROOT version 3.00/06)
//      from the StreamerInfo in file atlfast.root
/////////////////////////////////////////////////////////

#ifndef ATLFMuon_h
#define ATLFMuon_h

#include "TObject.h"
#include "TAtt3D.h"

class ATLFMuon : public TObject , public TAtt3D {
public:
  Int_t     m_KFcode; //Muon KF-code
  Int_t     m_MCParticle; //Muon position in MCParticles list
  Int_t     m_KFmother; //Muon mother KF-code
  Int_t     m_UseFlag; //Muon energy usage flag
  Int_t     m_Isolated; //Muon isolation (1 for isolated)
  Float_t   m_Eta; //Eta coordinate
  Float_t   m_Phi; //Phi coordinate
  Float_t   m_PT; //Transverse energy
  Int_t     m_Trigger; //Result of trigger

  ATLFMuon()   {;}
  virtual ~ATLFMuon()   {;}

  ClassDef(ATLFMuon,1) //
};

ClassImp(ATLFMuon)
#endif
```
Migrating to ROOT 3

We will distinguish the following cases:

**Case A**: You have your own `Streamer` method in your class implementation file. This also means that you have specified `MyClass` in the `LinkDef.h` file.
- keep `MyClass` unchanged
- Increment your class version id in `ClassDef` by 1, e.g. `ClassDef(MyClass, 2)`
- Change your `Streamer` function in the following way: The old write block can be replaced by the new standard Write. Change the read block to use the new scheme for the new versions and the old code for the old versions.

```cpp
def MyClass::Streamer(TBuffer &R__b)
{
    // Stream an object of class MyClass.
    if (R__b.IsReading()) {
        UInt_t R__s, R__c;
        Version_t R__v = R__b.ReadVersion(&R__s, &R__c);
        if (R__v > 1) {
            MyClass::Class()->ReadBuffer(R__b, this, R__v, R__s, R__c);
            return;
        }
        // process old versions before automatic schema evolution
        R__b >> xxxx;
        R__b >> .. etc
        R__b.CheckByteCount(R__s, R__c, MyClass::IsA());
    } else {
        MyClass::Class()->WriteBuffer(R__b, this);
    }
}
```

**Case B**: You use the automatic streamer in the dictionary file.
- Move the old Streamer from the file generated by `rootcint` to your class implementation file, then modify the `Streamer` function as in Case A above.
- Increment your class version id in `ClassDef` by 1, for example `ClassDef(MyClass, 2)`
- Add option `"-"` in the pragma line of `LinkDef`.

**Case C**: You use the automatic streamer in the dictionary file and you already use the option `"+"` in the `LinkDef` file. If the old automatic Streamer does not contain any statement using the function `WriteArray`, you have nothing to do, except running `rootcint` again to regenerate the new form of the `Streamer` function, otherwise proceed like for case B.

Compression and Performance

ROOT uses a compression algorithm based on the well-known `gzip` algorithm. It supports nine levels of compression. The default for ROOT is one.

The compression level can be set with the method `TFile::SetCompressionLevel`. Experience with this algorithm shows that a compression level of 1.3 for raw data files and around two on most DST files is the optimum. The choice of one for the default is a compromise between the time it takes to read and write the object vs. the disk space savings.

To specify no compression, set the level to zero.

We recommend using compression when the time spent in I/O is small compared to the total processing time. If the I/O operation is increased by a factor of 5 it is still a small percentage of the total time and it may compress the data by a factor of 10. On the other hand if the time spend on I/O is large, compression may have a large impact on the program's performance.

The compression factor, i.e. the savings of disk space, varies with the type of data. A buffer with a same value array is compressed so that the value is only written once. For example a track has the mass of a pion which it is always the same, and the charge of the pion which is either positive or negative. For 1000 pions, the mass will be written only once, and the charge only twice (positive and negative).

When the data is sparse, i.e. when there are many zeros, the compression factor is also high.

The time to uncompress an object is small compared to the compression time and is independent of the selected compression level. Note that the compression level may be changed at any time, but the new compression level will only apply to newly written objects. Consequently, a ROOT file may contain objects with different compression levels.

The compression factor, i.e. the savings of disk space, varies with the type of data. A buffer with a same value array is compressed so that the value is only written once. For example a track has the mass of a pion which it is always the same, and the charge of the pion which is either positive or negative. For 1000 pions, the mass will be written only once, and the charge only twice (positive and negative).

When the data is sparse, i.e. when there are many zeros, the compression factor is also high.

The time to uncompress an object is small compared to the compression time and is independent of the selected compression level. Note that the compression level may be changed at any time, but the new compression level will only apply to newly written objects. Consequently, a ROOT file may contain objects with different compression levels.

The time to uncompress an object is small compared to the compression time and is independent of the selected compression level. Note that the compression level may be changed at any time, but the new compression level will only apply to newly written objects. Consequently, a ROOT file may contain objects with different compression levels.

This table shows four runs of the demo script that creates 15 histograms with different compression parameters. To make the numbers more significant, the macro was modified to create 1000 histograms.

We have included two more examples to show the impact of compression on trees in the next chapter.

<table>
<thead>
<tr>
<th>Compression level</th>
<th>Bytes</th>
<th>Write Time (sec.)</th>
<th>Read Time (sec.)</th>
</tr>
</thead>
<tbody>
<tr>
<td>0</td>
<td>1,004,998</td>
<td>4.77</td>
<td>0.07</td>
</tr>
<tr>
<td>1</td>
<td>438,366</td>
<td>6.67</td>
<td>0.05</td>
</tr>
<tr>
<td>5</td>
<td>422,871</td>
<td>7.03</td>
<td>0.06</td>
</tr>
<tr>
<td>9</td>

</tr>
</tbody>
</table>

This table shows four runs of the demo script that creates 15 histograms with different compression parameters. To make the numbers more significant, the macro was modified to create 1000 histograms.

We have included two more examples to show the impact of compression on trees in the next chapter.
Accessing ROOT Files Remotely via a rootd

Reading and writing ROOT files over the net can be done by creating a TNetFile object instead of a TFile object. Since the TNetFile class inherits from the TFile class, it has exactly the same interface and behavior. The only difference is that it reads and writes to a remote rootd daemon.

TNetFile URL

TNetFile file names are in standard URL format with protocol "root". The following are valid TNetFile URL's:

- root://hpsalo/files/aap.root
- root://hpbrun.cern.ch/root/hsimple.root
- root://pcna49a:5151/~na49/data/run821.root
- root://pcna49d.cern.ch:5050//v1/data/run810.root

The only difference with the well-known httpd URL's is that the root of the remote file tree is the remote user's home directory. Therefore an absolute pathname requires a // after the host or port (as shown in the last example above). Further the expansion of the standard shell characters, like ~, $, .., etc. is handled as expected. The default port on which the remote rootd listens is 1094 and this default port is assumed by TNetFile (actually by TUrl which is used by TNetFile). The port number has been allocated by the IANA and is reserved for ROOT.

Remote Authentication

Connecting to a rootd daemon requires a remote user id and password. TNetFile supports three ways for you to provide your login information:

1. Setting it globally via the static TNetFile functions TNetFile::SetUser() and TNetFile::SetPasswd()
2. Via the ~/.netrc file (same format and file as used by ftp)
3. Via command line prompt

The different methods will be tried in the order given above. On machines with AFS, rootd will obtain an AFS token.

A Simple Session

root [] TFile *f1 = TFile::Open("local/file.root", "update")
root [] TFile *f2 = TFile::Open("root://pcna49a.cern.ch/data/file.root", "new")
Name (pcna49a:rdm):
Password:
root [] TFile *f3 = TFile::Open("http://root.cern.ch/~rdm/hsimple.root")
TWebFile* http://root.cern.ch/~rdm/hsimple.root
KEY: TH1F hpx;1 This is the px distribution
KEY: TH2F hpxpy;1 py vs px
KEY: TProfile hprof;1 Profile of px versus px
KEY: TNamed ntuple;1 Demo ntuple
root [] hpx.Draw()

The rootd Daemon

The rootd daemon works with the TNetFile class. It allows remote access to ROOT database files in read or read/write mode. The rootd daemon can be found in the directory $ROOTSYS/bin. It can be started either via inetd or by hand from the command line (no need to be super user). Its performance is comparable with NFS but while NFS requires all kind of system permissions to setup, rootd can be started by any user. The simplest way to start rootd is by starting it from the command line while being logged in to the remote machine. Once started rootd goes immediately in the background (no need for the &). You can log out from the remote node. The only argument required is the port number (1094) on which your private rootd will listen. Using TNetFile you can now read and write files on the remote machine.

For example:

hpsalo [] telnet fsgi02.fnal.gov
login:
minuser
Password:
<fgsl02> rootd -p 1094
<fgsl02> exit

hpsalo [] root
root [] TFile *f = TFile::Open("/hpsalo/files/aap.root", "new")
Name (fsgi02.fnal.gov:rdm): minuser
Password:
root [] f.ls()

In the above example, rootd runs on the remote node under user id minuser and listens to port 1094. When creating a TNetFile object you have to specify the same port number 1094 and use minuser (and corresponding password) as login id. When rootd is started in this way, you can only login with the user id under which rootd was started on the remote machine. However, you can make many connections since the original rootd will fork (spawn) a new rootd that will service the requests from the TNetFile. The original rootd keeps listening on the specified port for other connections. Each time a TNetFile makes a connection, it gets a new private rootd that will handle its requests. At the end of a ROOT session when all TNetFiles are closed only the original rootd will stay alive ready to service future TNetFiles.
Starting rootd via inetd

If you expect to often connect via TNetFile to a remote machine, it is more efficient to install rootd as a service of the inetd super daemon. In this way, it is not necessary for each user to run a private rootd. However, this requires a one-time modification of two system files (and super user privileges to do so). Add to /etc/services the line:

rootd 1094/tcp

To /etc/inetd.conf the line:

rootd stream tcp nowait root /usr/local/root/bin/rootd rootd -i

After these changes force inetd to reread, its config file with "kill -HUP <pid inetd>".

When setup in this way it is not necessary to specify a port number in the URL given to TNetFile. TNetFile assumes the default port to be 1094 as specified above in the /etc/services file.

Command Line Arguments for rootd

rootd support the following arguments:

-1 says we are started by inetd

-p port# specifies port number to listen on

-d level level of debug info written to syslogd
0 = no debug (default)
1 = minimum
2 = medium
3 = maximum

Reading ROOT Files via Apache Web Server

By adding one ROOT specific module to your Apache web server, you can distribute ROOT files to any ROOT user. There is no longer a need to send your files via FTP and risking (out of date) histograms or other objects. Your latest up-to-date results are always accessible to all your colleagues.

To access ROOT files via a web server, create a TWebFile object instead of a TFile object with a standard URL as file name. For example:

```cpp
root [] TWebFile f(*"http://root.cern.ch/~rdm/hsimple.root")
root [] f.ls()
```

Since TWebFile inherits from TFile all TFile operations work as expected. However, due to the nature of a web server a TWebFile is a read-only file. A TWebFile is ideally suited to read relatively small objects (like histograms or other data analysis results). Although possible, you don't want to analyze large TTrees via a TWebFile.

Here follows a step-by-step recipe for making your Apache 1.1 or 1.2 web server ROOT aware:

1. Go to your Apache source directory and add the file http://root.cern.ch/root/mod_root.c or http://root.cern.ch/root/mod_root133.c when your Apache server is > 1.2 (rename the file mod_root.c).
2. Add to the end of the Configuration file the line:
   Module root_module mod_root.o
3. Run the Configure script
4. Type make
5. Copy the new httpd to its expected place
6. Go to the conf directory and add at the end of the srm.conf file the line:
   AddHandler root-action root
7. Restart the httpd server

Using the General TFile::Open() Function

To make life simple we provide a general function to open any type of file (except shared memory files of class TMapFile). This functionality is provided by the static TFile::Open() function:

```cpp
TFile *TFile::Open(const Text_t *name, Option_t *option="", const Text_t *title="");
```

Depending on the name argument, the function returns a TFile, a TNetFile or a TWebFile object. In case a TNetFile URL specifies a local file, a TFile object will be returned (and of course no login information is needed). The arguments of the Open() function are the same as the ones for the TFile constructor.
In the Input/Output chapter, we saw how objects can be saved in ROOT files. In case you want to store large quantities of same-class objects, ROOT has designed the TTree and TNtuple classes specifically for that purpose. The TTree class is optimized to reduce disk space and enhance access speed. A TNtuple is a TTree that is limited to only hold floating-point numbers; a TTree on the other hand can hold all kind of data, such as objects or arrays in addition to all the simple types.

When using a TTree, we fill its branch buffers with leaf data and the buffers are written to file when it is full. Branches, buffers, and leafs, are explained a little later in this chapter, but for now, it is important to realize that not each object is written individually, but rather collected and written a bunch at a time. This is where the TTree takes advantage of compression and will produce a much smaller file than if the objects were written individually. Since the unit to be compressed is a buffer, and the TTree contains many same-class objects, the header of the objects can be compressed. The TTree reduces the header of each object, but it still contains the class name. Using compression, the class name of each same-class object has a good chance of being compressed, since the compression algorithm recognizes the bit pattern representing the class name. Using a TTree and compression the header is reduced to about 4 bytes compared to the original 60 bytes. However, if compression is turned off, you will not see these large savings.

The TTree is also used to optimize the data access. A tree uses a hierarchy of branches, and each branch can be read independently from any other branch. Now, assume that $P_x$ and $P_y$ are data members of the event, and we would like to compute $P_x^2 + P_y^2$ for every event and histogram the result. If we had saved the million events without a TTree we would have to: 1) read each event in its entirety into memory, 2) extract the $P_x$ and $P_y$ from the event, 3) compute the sum of the squares, and 4) fill a histogram. We would have to do that a million times! This is very time consuming, and we really do not need to read the entire event, every time. All we need are two little data members ($P_x$ and $P_y$). On the other hand, if we use a tree with one branch containing $P_x$ and another branch containing $P_y$, we can read all values of $P_x$ and $P_y$ by only reading the $P_x$ and $P_y$ branches. This makes the use of the TTree very attractive.

### A Simple TTree

This script builds a TTree from an ASCII file containing statistics about the staff at CERN. This script, staff.C and its input file staff.dat are in $ROOTSYS/tutorials.

```c
// example of macro to read data from an ascii file and
// create a root file with an histogram and a TTree.
gROOT->Reset();

// the structure to hold the variables for the branch
struct staff_t {
    Int_t cat;
    Int_t division;
    Int_t flag;
    Int_t age;
    Int_t service;
    Int_t children;
    Int_t grade;
    Int_t step;
    Int_t nation;
    Int_t hrweek;
    Int_t cost;
};
staff_t staff;

// open the ascii file
FILE *fp = fopen("staff.dat","r");
char line[81];

// create a new ROOT file
TFile *f = new TFile("staff.root","RECREATE");

// create a TTree
TTree *tree = new TTree("tree",
"staff data from ascii file");

// create one branch with all the information from
// the structure
tree->Branch("staff", &staff.cat,"I:division:
flag:age:service:children:grade:step:
nation:hrweek:cost");

// fill the tree from the values in ASCI file
while (fgets(line,81,fp)) {
    sscanf(line,"%d%d%d%d",
&staff.cat,&staff.division,&staff.flag,&staff.age);
    sscanf(line,"%d%d%d",
&staff.children,&staff.grade,&staff.step);
    sscanf(line,"%d%d%d",
&staff.nation,&staff.hrweek,&staff.cost);
    tree->Fill();
}

// check what the tree looks like
tree->Print();
fclose(fp);
f->Write();
```
The script declares a structure called `staff_t`, with several integers representing the relevant attribute of a staff member.

The script opens the ASCII file, creates a ROOT file and a TTree. Then it creates one branch with the `TTree::Branch` method.

The first parameter of the `Branch` method is the branch name. The second parameter is the address from which the first leaf is to be read. In this example it is the address of the structure `staff`.

Once the branch is defined, the script reads the data from the ASCII file into the `staff_t` structure and fills the tree.

The ASCII file is closed, and the ROOT file is written to disk saving the tree.

Remember, trees and histograms are created in the current directory, which is the file in our example. Hence an `f->Write()` saves the tree.

### Show An Entry with TTree::Show

An easy way to access one entry of a tree is the use the `TTree::Show` method. For example to look at the 10th entry in the `staff.root` tree:

```cpp
root[] TFile f("staff.root")
root[] tree->Show(10)
```

```
EVTN:10 c t = 361
division = 9
flag = 15
age = 51
service = 29
children = 0
grade = 7
step = 13
nation = 7
hrweek = 40
cost = 7599
```

### Print the tree structure with TTree::Print

A helpful command to see the tree structure meaning the number of entries, the branches and the leaves, is `TTree::Print`.

```cpp
root[] tree->Print()
```

```
Tree tree = staff data from ascii file
*Entries:3354 Total = 334680 bytes File Size = 46302
  Tree compression factor = 3.24
  *Xr 0:staff cat/I:division:flag:age:service:children:grade:step:
    nation:hrweek:cost
*Entries:3354 Total Size = 127856 bytes File Size = 39478
  *Baskets: 4 Basket Size = 32000 bytes Compression: 3.24
```
Here is what the tree viewer looks like for the example file `staff.root`.

The left panel contains the list of trees and their branches, in this case there is only one tree. You can add more trees with the File-Open command to open the file containing the new tree, then use the context menu on the right panel, select SetTreeName and enter the name of the tree to add.

On the right are the leaves or variables in the tree. You can double click on any leaf to a histogram it.

To draw more than one dimension you can drag and drop any leaf to the X, Y, and Z "boxes". Then push the Draw button, which is marked with the purple icon on the bottom left.

To add a cut/weight to the histogram, enter an expression in the "cut box". The cut box is the one with the scissor icon.

You can create a new expression by right clicking on any of the E() boxes. The expression can be dragged and dropped into any of the boxes (X, Y, Z, Cut, or Scan).

To scan one or more variables, drop them into the Scan box, then double click on the box. You can also redirect the result of the scan to a file by checking the Scan box on top.

When the "Rec" box is checked, the Draw and Scan commands are recorded in the history file and echoed on the command line.

The "Histogram" text box contains the name of the resulting histogram. By default it is `htemp`. You can type any name, if the histogram does not exist it will create one.

The Option text box contains the list of Draw options (see Draw Options in the Histogram Chapter). You can select the options with the Options menu.

The Command box lets you enter any command that you could also enter on the command line.
Creating and Saving Trees

This picture shows the TTree class:

Creating a Tree from a Folder Hierarchy

An alternative way to create a tree and organize it is to use folders. You can build a folder structure (see the chapter on Folders and Tasks), and create a tree with branches for each of the sub-folders:

```cpp
TTree folder_tree("MyFolderTree", "/MyFolder")
```

The second argument is the top folder, and the "/" signals the TTree constructor that this is a folder not just the title. You fill the tree by placing the data into the folder structure and calling TTree::Fill.

The reverse is also true, one can recreate the folder hierarchy from the tree with the TTree::SetFolder method.

Autosave

Autosave gives the option to save all branch buffers every n byte. We recommend using Autosave for large acquisitions. If the acquisition fails to complete, you can recover the file and all the contents since the last Autosave. To set the number of bytes between Autosave you can use the TTree::SetAutosave() method. You can also call TTree::Autosave in the acquisition loop every n entry.

Branches

The class for a branch is called TBranch. The organization of branches allows the designer to optimize the data for the anticipated use.

If two variables are independent, and the designer knows the variables will not be used together, she would place them on separate branches. If, however, the variables are related, such as the coordinates of a point, it is most efficient to create one branch with both coordinates on it. A variable on a TBranch is called a leaf (yes - TBranch).

Another point to keep in mind when designing trees is the branches of the same TTree can be written to separate files.

To add a TBranch to a TTree we call the TTree::Branch() method. Note that we DO NOT use the TBranch constructor.

The TBranch::Branch method has several signatures. The branch type differs by what is stored in it. A branch can hold an entire object, a list of simple variables, contents of a folder, contents of a TBranch, or an array of objects. Let's see some examples.

To follow along you will need the shared library libEvent.so. First, check if it is in $ROOTSYS/test. If it is, copy it to your own area. If it is not there, you have to build it.
Adding a Branch to hold a List of Variables

As in the very first example (`staff.root`) the data we want to save is a list of simple variables, such as integers or floats. In this case, we use the following TTree::Branch signature:

```
  tree->Branch("Ev_Branch", &event, "temp/F:ntrack/I:nseg:nvtex:flag/i ");
```

The first parameter is the branch name. The second parameter is the address from which the first variable is to be read. In the code above, “event” is a structure with one float and three integers and one unsigned integer. You should not assume that the compiler aligns the elements of a structure without gaps. To avoid alignment problems, you need to use structures with same length members. If your structure does not qualify, you need to create one branch for each element of the structure.

The leaf name is NOT used to pick the variable out of the structure, but is only used the name for the leaf. This means that the list of variables needs to be in a structure in the order described in the third parameter.

This third parameter is a string describing the leaf list. Each leaf has a name and a type separated by a "/" and it is separated from the next leaf by a ":".

```
<Variable>/<type>:<Variable>/<type>
```

The example on the next line has two leafs: a floating-point number called `temp` and an integer named `ntrack`.

```
  "temp/F:ntrack/I:"
```

The type can be omitted and if no type is given, the same type as the previous variable is assumed. This leaf list has three integers called `ntrack`, `nseg`, and `nvtex`.

```
<ntrack/I:nseg:nvtex>
```

There is one more rule: when no type is given for the very first leaf, it becomes a `float` (F). This leaf list has three floats called `temp`, `mass`, and `px`.

```
"temp:mass:px"
```

The symbols used for the type are:

- C: a character string terminated by the 0 character.
- B: an 8 bit signed integer.
- b: an 8 bit unsigned integer.
- S: a 16 bit signed integer.
- s: a 16 bit unsigned integer.
- L: a 32 bit signed integer.
- i: a 32 bit unsigned integer.
- F: a 32 bit floating point.
- D: a 64 bit floating point.

Adding a TBranch to hold an Object

To write a branch to hold an event object, we need to load the definition of the Event class, which is in `$ROOTSYS/test/libEvent.so`. For an object to be in a tree its class definition needs to include the ClassDef/ClassImp macros. We expect to remove this restriction in the near future.

```
  root [] .L libEvent.so
```

First, we need to open a file and create a tree.

```
  root [] TPFile *f = new TPFile("AFile.root", "RECREATE");
  Int_t nPhot;
  Float_t *E = new Float_t[500];
  TTree* nEmcPhotons = new TTree("nEmcPhotons","EMC Photons");
  nEmcPhotons->Branch("nPhot", &nPhot, "nPhot/I");
  nEmcPhotons->Branch("E","E[nPhot]/F");
```

For an example see Example 2 below (`$ROOTSYS/tutorials/tree2.C`) and `staff.C` at the beginning of this chapter.

The type is used for a byte count to decide how much space to allocate. The variable written is simply the block of bytes starting at the starting address given in the second parameter. It may or may not match the leaf list depending on whether or not the programmer is being careful when choosing the leaf address, name, and type.

By default, a variable will be copied with the number of bytes specified in the type descriptor symbol. However, if the type consists of two characters, the number specifies the number of bytes to be used when copying the variable to the output buffer. The line below describes `ntrack` to be written as a 16-bit integer (rather than a 32-bit integer).

```
  "ntrack/I2"
```

With this Branch method, you can also add a leaf that holds an entire array of variables. To add an array of floats use the `f[n]` notation when describing the leaf.

```
  Float_t *f[10];
  tree->Branch("fBranch", &f,"f[10]/F");
```

You can also add an array of variable length:

```
  { 
    TPFile *f = new TPFile("peter.root", "recreate");
    Int_t nPhot;
    Float_t *E = new Float_t[500];
    TTree* nEmcPhotons = new TTree("nEmcPhotons","EMC Photons");
    nEmcPhotons->Branch("nPhot", &nPhot, "nPhot/I");
    nEmcPhotons->Branch("E","E[nPhot]/F");
  }
```

For an example see Example 2 below (`$ROOTSYS/tutorials/tree2.C`) and `staff.C` at the beginning of this chapter.
We need to create a pointer to an `Event` object that will be used as a reference in the `TTree::Branch` method. Then we create a branch with the `TTree::Branch` method.

```c++
root[1] Event *event = new Event()

```

To add a branch to hold an object we use the signature above. The first parameter is the name of the branch. The second parameter is the name of the class of the object to be stored. The third parameter is the address of a pointer to the object to be stored.

The fourth parameter is the buffer size and is by default 32000 bytes. It is the number of bytes of data for that branch to save to a buffer until it is saved to the file.

The last parameter is the split-level, which is the topic of the next section.

Static class members are not part of an object and thus not written with the object. You could store them separately by collecting these values in a special "status" object and write it to the file outside of the tree. If it makes sense to store them for each object, make them a regular data member.

### Setting the Split-level

To split a branch means to create a sub-branch for each data member in the object. The split-level can be set to 0 to disable splitting or it can be set to a number between 1 and 99 indicating the depth of splitting.

If the split-level is set to zero, the whole object is written in its entirety to one branch. The `TTree` will look like the one on the right, with one branch and one leaf holding the entire event object.

A tree that is split

A tree that is not split

When the split level is 1, an object data member is assigned a branch. If the split level is 2, the data member objects will be split also, and a split level of 3 its data members objects, will be split. As the split level increases so does the splitting depth.

ROOT's default for the split level is 99, this means the object will be split to the maximum.

### Memory Considerations when Splitting a Branch

Splitting a branch can quickly generate many branches. Each branch has its own buffer in memory. In case of many branches (say more than 100), you should adjust the buffer size accordingly. A recommended buffer size is 32000 bytes if you have less than 50 branches. Around 16000 bytes if you have less than 100 branches and 4000 bytes if you have more than 500 branches. These numbers are recommended for computers with memory size ranging from 32MB to 256MB. If you have more memory, you should specify larger buffer sizes. However, in this case, do not forget that your file might be used on another machine with a smaller memory configuration.

### Performance Considerations when Splitting a Branch

A split branch is faster to read, but slightly slower to write. The reading is quicker because variables of the same type are stored consecutively and the type does not have to be read each time. It is slower to write because of the large number of buffers as described above. See Performance Benchmarks for performance impact of split and non-split mode.

### Rules for Splitting

When splitting a branch, variables of different types are handled differently. Here are the rules that apply when splitting a branch.

- If a data member is a basic type, it becomes one branch of class `TBranchElement`.
- A data member can be an array of basic types. In this case, one single branch is created for the array.
- A data member can be a pointer to an array of basic types. The length can vary, and must be specified in the comment field of the data member in the class definition. (see I/O chapter).
- Pointer data member are not split, except for pointers to a `TClonesArray`. The `TClonesArray` (pointed to) is split if the split level is greater than two. When the split level is one, the `TClonesArray` is not split.
- If a data member is a pointer to an object, a special branch is created. The branch will be filled by calling the class `Streamer` function to serialize the object into the branch buffer.
- If a data member is an object, the data members of this object are split into branches according to the split level (i.e. split level > 2).
- Base classes are split when the object is split.
- Abstract base classes are never split.
- Most STL containers are supported except for some extreme cases. These examples are not supported:

```
// STL vector of vectors of TAxis*
vector<vector<TAxis *> > fVectAxis;

// STL map of string/vector
map<string,vector<int> > fMapString;

// STL deque of pair
deque<pair<float,float> > fDequePair;
```

- C-structure data members are not supported in split mode.
- An object that is not split may be slow to browse.
- An STL container that is not split will not be accessible in the browser.
Exempt a Data Member from Splitting
If you are creating a branch with an object and in general you want the data members to be split, but you want to exempt a data member from the split. You can specify this in the comment field of the data member:

class Event : public TObject {
  public:
  ;
  private:
  EventHeader fEvtHdr;  //|| Don't split the header
};

Adding a Branch to hold a TClonesArray
ROOT has two classes to manage arrays of objects. The TObjArray that can manage objects of different classes, and the TClonesArray that specializes in managing objects of the same class (hence the name Clones Array). TClonesArray takes advantage of the constant size of each element when adding the elements to the array. Instead of allocating memory for each new object as it is added, it reuses the memory. Here is an example of the time a TClonesArray can save over a TObjArray.

We have 100,000 events, and each has 10,000 tracks, which gives 1,000,000,000 tracks. If we use a TObjArray for the tracks, we implicitly make a call to new and a corresponding call to delete for each track. The time it takes to make a pair of new/delete calls is about 7 µs (10^-6). If we multiply the number of tracks by 7 µs, (1,000,000,000 * 7 * 10^-6) we calculate that the time allocating and freeing memory is about 2 hours. This is the chunk of time saved when a TClonesArray is used rather than a TObjArray. If you don't want to wait 2 hours for your tracks (or equivalent objects), be sure to use a TClonesArray for same-class objects arrays.

Branches with TClonesArrays use the same method (TTree::Branch) as any other object described above. If splitting is specified the objects in the TClonesArray are split, not the TClonesArray itself.

Identical Branch Names
When a top-level object (say Event) has two data members of the same class the sub branches end up with identical names. To distinguish the sub branch we must associate them with the master branch by including a ":" (dot) at the end of the master branch name. This will force the name of the sub branch to be master:sub branch instead of simply sub branch.

For example, a tree has two branches Trigger and MuonTrigger, each containing an object of the same class (Trigger). To uniquely identify the sub branches we add the dot:

tree->Branch("Trigger.","Trigger",&b1,8000,1);
tree->Branch("MuonTrigger.","Trigger",&b2,8000,1);

If Trigger has three members, T1, T2, T3, the two instructions above will generate sub branches called:
Trigger.T1, Trigger.T2, Trigger.T3,
MuonTrigger.T1, MuonTrigger.T2, MuonTrigger.T3.

Adding a Branch with a Folder
To add a branch from a folder use the syntax:

tree->Branch("/aFolder");

This method creates one branch for each element in the folder. The method returns the total number of branches created.

Adding a Branch with a Collection
This Branch method creates one branch for each element in the collection.

tree->Branch("aCollection, 8000, 99);

The method returns the total number of branches created. Each entry in the collection becomes a top level branch if the corresponding class is not a collection. If it is a collection, the entry in the collection becomes in turn top level branches, etc. The split level is decreased by 1 every time a new collection is found. For example if list is a TObjArray

• if splitlevel = 1, one top level branch is created for each element of the TObjArray.
• if splitlevel = 2, one top level branch is created for each array element. If, in turn, one of the array elements is a TCollection, one top level branch will be created for each element of this collection.

In case a collection element is a TClonesArray, the special Tree constructor for TClonesArray is called. The collection itself cannot be a TClonesArray.

If name is given, all branch names will be prefixed with name_.

IMPORTANT NOTE1: This function should not be called with splitlevel < 1.

IMPORTANT NOTE2: The branches created by this function will have names corresponding to the collection or object names. It is important to give names to collections to avoid misleading branch names or identical branch names. By default collections have a name equal to the corresponding class name, e.g. the default name for a TList is "TList".

Examples For Writing and Reading Trees
The following sections are examples of writing and reading trees increasing in complexity from a simple tree with a few variables to a tree containing folders and complex Event objects.

Each example has a named script in the $ROOTSYS/tutorials directory. They are called tree1.C to tree4.C. The examples are:

• tree1.C: A tree with several simple (integers and floating point) variables.
• tree2.C: A tree built from a C structure (struct). This example uses the Geant3 C wrapper as an example of a Fortran common block ported to C with a C structure.
• tree3.C: In this example we will show how to extend a tree with a branch from another tree with the Friends feature. These trees have branches with variable length arrays. Each entry has a variable number of tracks, and each track has several variables.

• tree4.C: A tree with a class (Event). The class Event is defined in $ROOTSYS/test. In this example we first encounter the impact of splitting a branch.

Each script contains the main function, with the same name as the file (i.e. tree1), the function to write - tree1w, and the function to read - tree1r. If the script is not run in batch mode, it displays the tree in the browser and tree viewer.

To study the example scripts, you can either execute the main script, or load the script and execute a specific function. For example:

```c
// execute the tree1() function
// that writes, reads, and shows the tree
root [] .x tree1.C
// use ACLiC to build a shared library and
// check syntax, then execute as above
root [] .x tree1.C++
// Load the script and select a function to execute
root [] .L tree1.C
root [] tree1w()
root [] tree1r()
```

### Example 1: A Tree with Simple Variables

This example shows how to write, view, and read a tree with several simple (integers and floating point) variables.

#### Writing the Tree

Below is the function that writes the tree (tree1w). First, the variables are defined (px, py, pz, random and ev). Then we add a branch for each of the variables to the tree, by calling the `TTree::Branch` method for each variable.

```c
void tree1w()
{
    // create a Tree file tree1.root
    // create the file, the Tree and a few branches
    TFile f("tree1.root","recreate");
    TTree t1("t1","a simple Tree with simple variables");
    Float_t px, py, pz;
    Double_t random;
    Int_t ev;
    t1.Branch("px", &px, "px/F");
    t1.Branch("py", &py, "py/F");
    t1.Branch("pz", &pz, "pz/F");
    t1.Branch("random", &random, "random/F");
    t1.Branch("ev", &ev, "ev/I");
    // continued on the next page …
}
```

#### Filling the Tree

First we find some random values for the variables. We assign px and py a gaussian with mean = 0 and sigma = 1 by calling `gRandom->Rannor(px, py)`, and calculate pz. Then we call the `TTree::Fill` method. Because we have already organized the tree into branches and told each branch where to get the value from, the call `t1.Fill();` fills all branches in the tree.

After this script is executed we have a ROOT file called `tree1.root` with a tree called `t1`.

```c
//fill the tree
for (Int_t i=0;i<10000;i++)
{
    gRandom->Rannor(px,py);
    pz = px*px + py*py;
    random = gRandom->Rndm();
    ev = i;
    t1.Fill();
}
```

```c
//save the Tree header.
//The file will be automatically closed
// when going out of the function scope
//t1.Write();
```

```c
Creating Branches with A single Variable

This is the signature of `TTree::Branch` to create a branch with a list of variables:

```c
TBranch* TTree::Branch(const char* name, void* address, const char* leaflist, Int_t bufsize = 32000)
```

The first parameter is the branch name.
The second parameter is the address from which to read the value.
The third parameter is the leaf list with the name and type of each leaf.
In this example each branch has only one leaf. In the box below, the branch is named `px` and has one floating point type leaf also called `px`.

```c
t1.Branch("px", &px, "px/F");
```
```c
Example 1: A Tree with Simple Variables

This example shows how to write, view, and read a tree with several simple (integers and floating point) variables.

#### Writing the Tree

Below is the function that writes the tree (tree1w). First, the variables are defined (px, py, pz, random and ev). Then we add a branch for each of the variables to the tree, by calling the `TTree::Branch` method for each variable.

```c
void tree1w()
{
    // create a Tree file tree1.root
    // create the file, the Tree and a few branches
    TFile f("tree1.root","recreate");
    TTree t1("t1","a simple Tree with simple variables");
    Float_t px, py, pz;
    Double_t random;
    Int_t ev;
    t1.Branch("px", &px, "px/F");
    t1.Branch("py", &py, "py/F");
    t1.Branch("pz", &pz, "pz/F");
    t1.Branch("random", &random, "random/F");
    t1.Branch("ev", &ev, "ev/I");
    // continued on the next page …
}
```

```c
// continued from previous page
for (Int_t i=0;i<10000;i++)
{
    gRandom->Rannor(px,py);
    pz = px*px + py*py;
    random = gRandom->Rndm();
    ev = i;
    t1.Fill();
}
```

```c
Creating Branches with A single Variable

This is the signature of `TTree::Branch` to create a branch with a list of variables:

```c
TBranch* TTree::Branch(const char* name, void* address, const char* leaflist, Int_t bufsize = 32000)
```

The first parameter is the branch name.
The second parameter is the address from which to read the value.
The third parameter is the leaf list with the name and type of each leaf.
In this example each branch has only one leaf. In the box below, the branch is named `px` and has one floating point type leaf also called `px`.

```c
t1.Branch("px", &px, "px/F");
```
Viewing the Tree

This is the `tree1.root` file and its tree in the browser.

In the right panel are the branches `ev`, `px`, `py`, `pz`, and `random`. Note that these are shown as leaves because they are "end" branches with only one leaf.

To histogram a leaf we can simply double click on it in the browser:

This is how the tree looks in the Tree Viewer. Here we can add a cut and add other operations for histogramming the leaves (see the section on Tree Viewer). For example, we can plot a two dimensional histogram.

Reading the Tree

The `tree1r` function shows how to read the tree and access each entry and each leaf.

We first define the variables to hold the read values.

```cpp
Float_t px, py, pz;
```

Then we tell the tree to populate these variables when reading an entry. We do this with the `TTree::SetBranchAddress` method. The first parameter is the branch name, and the second is the address of the variable where the branch data is to be placed.

In this example the branch name is `px`. This name was given when the tree was written (see `tree1w`). The second parameter is the address of the variable `px`.

```cpp
t1->SetBranchAddress("px", &px);
```

`GetEntry`

Once the branches have been given the address, a specific entry can be read into the variables with the method `TTree::GetEntry(n)`. The `TTree::GetEntry` method reads all the branches for entry (n) and populates the given address accordingly.

By default, `GetEntry()` reuses the space allocated by the previous object for each branch. You can force the previous object to be automatically deleted if you call `mybranch.SetAutoDelete(kTRUE)` (default is `kFALSE`).

Example:

Consider the example in `$ROOTSYS/test/Event.h`. The top level branch in the tree `T` is declared with:

```cpp
Event *event = 0;
//event must be null or point to a valid object
//it must be initialized
T.SetBranchAddress("event", &event);
```

When reading the Tree, one can choose one of these 3 options:

Option 1:

```cpp
for (Int_t i=0; i<nentries; i++) {
  T.GetEntry(i);
  //the object event has been filled at this point
}
```

The is the default and recommended. At the first entry an object of the class `Event` will be created and pointed by `event`.

At the following entries, `event` will be overwritten by the new data. All internal members that are `TObject` are automatically deleted. It is important
that these members be in a valid state when GetEntry is called. Pointers must be correctly initialized.

However these internal members will not be deleted if the characters ‘->’ are specified as the first characters in the comment field of the data member declaration.

If ‘->’ is specified, the pointer member is read via $pointer->Streamer(buf)$. In this case, it is assumed that the pointer is never null (see pointer TClonesArray *fTracks in the $ROOTSYS/test/Event example).

If ‘->’ is not specified, the pointer member is read via buf >> pointer. In this case the pointer may be null. Note that the option with ‘->’ is faster to read or write and it also consumes less space in the file.

**Option 2:**
The option AutoDelete is set:

```
TBranch *branch = T.GetBranch("event");
branch->SetAddress(&event);
for (Int_t i=0;i<nentries;i++) {
    T.GetEntry(i);
    // the object event has been filled at this point
}
```

In this case, at each iteration, the object event is deleted by GetEntry and a new instance of Event is created and filled.

**Option 3:**
Same as option 1, but you delete yourself the event:

```
for (Int_t i=0;i<nentries;i++) {
    delete event;
    event = 0; EXTREMELY IMPORTANT
    T.GetEntry(i);
    the object event has been filled at this point
}
```

It is strongly recommended to use the default option 1. It has the additional advantage that functions like TTree::Draw (internally calling TTree::GetEntry) will be functional even when the classes in the file are not available.

Reading selected branches is quicker than reading an entire entry. If you are interested in only one branch, you can use the TBranch::GetEntry method and only that branch is read.

---

Here is the script `tree1r`:

```c
void tree1r()
{
    //read the Tree generated by tree1w
    //and fill two histograms
    
    //note that we use "new" to create the TFile
    //and TBranch objects, because we want to keep
    //these objects alive when we leave this function.
    TFile *f = new TFile("tree1.root");
    TBranch *t1 = (TBranch*)f->Get("t1");
    Float_t px, py, pz;
    Double_t random;
    Int_t ev;
    t1->SetBranchAddress("px", &px);
    t1->SetBranchAddress("py", &py);
    t1->SetBranchAddress("pz", &pz);
    t1->SetBranchAddress("random", &random);
    t1->SetBranchAddress("ev", &ev);

    //create two histograms
    TH1F *hpx = new TH1F("hpx","px distribution",100,-3,3);
    TH2F *hpxpy = new TH2F("hpxpy","py vs px",30,-3,3,30,-3,3);

    //read all entries and fill the histograms
    Int_t nentries = (Int_t)t1->GetEntries();
    for (Int_t i=0;i<nentries;i++) {
        t1->GetEntry(i);
        hpx->Fill(px);
        hpxpy->Fill(px,py);
    }

    //we do not close the file.
    //We want to keep the generated histograms
    //we open a browser and the TreeViewer
    if (gROOT->IsBatch()) return;
    new TBrowser();
    t1->StartViewer();
    //In the browser, click on "ROOT Files",
    //then on "tree1.root".
    //You can click on the histogram icons
    //in the right panel to draw them.
    //In the TreeViewer, follow the instructions
    //in the Help button.
}
```
Example 2: A Tree with a C Structure

The executable script for this example is $ROOTSYS/tutorials/tree2.C. In this example we show:

- how to build branches from a C structure
- how to make a branch with a fixed length array
- how to make a branch with a variable length array
- how to read selective branches
- how to fill a histogram from a branch
- how to use TTree::Draw to show a 3D plot.

A C structure (struct) is used to build a ROOT tree. In general we discourage the use of C structures, we recommend using a class instead. However, we do support them for legacy applications written in C or Fortran.

The example struct holds simple variables and arrays. It maps to a Geant3 common block /gctrak/. This is the definition of the common block/structure:

```c
typedef struct {
  Float_t  vect[7];
  Float_t  getot;
  Float_t  gekin;
  Float_t  vout[7];
  Int_t    nmec;
  Int_t    lmec[MAXMEC];
  Int_t    namec[MAXMEC];
  Int_t    nstep;
  Int_t    pid;
  Float_t  destep;
  Float_t  destel;
  Float_t  safety;
  Float_t  sleng;
  Float_t  step;
  Float_t  snext;
  Float_t  sfield;
  Float_t  tofg;
  Float_t  gekrat;
  Float_t  upwght;
} Gctrak_t;
```

void helixStep(Float_t step, Float_t *vect, Float_t *vout) {
  // extrapolate track in constant field
  Float_t field = 20;   // field in kilogauss
  enum Evect {kX,kY,kZ,kPX,kPY,kPZ,kPP};
  vout[kPP] = vect[kPP];
  Float_t h4 = field*2.99792e-4;
  Float_t rho = -h4/vect[kPP];
  Float_t tet = rho*step;
  Float_t tsint = tet*tet/6;
  Float_t sintt = 1 - tsint;
  Float_t sint = tet*sintt;
  Float_t cos1t = tet/2;
  Float_t f1 = step*sintt;
  Float_t f2 = step*cos1t;
  Float_t f3 = step*tsint*vect[kPP];
  Float_t f4 = -tet*cos1t;
  Float_t f5 = sint;
  Float_t f6 = tet*cos1t*vect[kPP];
  vout[kX] = vect[kX] + (f1*vect[kPX] - f2*vect[kPY]);
  vout[kY] = vect[kY] + (f1*vect[kPY] + f2*vect[kPX]);
  vout[kZ] = vect[kZ] + (f1*vect[kPZ] + f3);
  vout[kPX] = vect[kPX] + (f4*vect[kPX] - f5*vect[kPY]);
  vout[kPY] = vect[kPY] + (f4*vect[kPY] + f5*vect[kPX]);
  vout[kPZ] = vect[kPZ] + (f4*vect[kPZ] + f6);
}
```

When using Geant3, the common block is filled by Geant3 routines at each step and only the TTree::Fill method needs to be called. In this example we emulate the Geant3 step routine with the helixStep function. We also emulate the filling of the particle values. The calls to the Branch methods are the same as if Geant3 were used.
Writing The Tree

```c
void tree2w() // write tree2 example
{
    //create a Tree file tree2.root
    TFile f("tree2.root","recreate");
    //create the file, the Tree
    TTree t2("t2","a Tree with data from a fake Geant3");
    // declare a variable of the C structure type
    Gctrak_t gstep;
    // add the branches for a subset of gstep
    t2.Branch("vect",&gstep.vect,"vect[7]/F");
    t2.Branch("getot",&gstep.getot,"getot/F");
    t2.Branch("gekin",&gstep.gekin,"gekin/F");
    t2.Branch("nmec",&gstep.nmec,"nmec/I");
    t2.Branch("destep",&gstep.destep,"destep/F");
    t2.Branch("pid",&gstep.pid,"pid/I");
    //Initialize particle parameters at first point
    Float_t px,py,pz,p,charge=0;
    Float_t vout[7];
    Float_t mass = 0.137;
    Bool_t newParticle = kTRUE;
    gstep.step = 0.1;
    gstep.destep = 0;
    gstep.nmec = 0;
    gstep.pid = 0;
    //transport particles
    for (Int_t i=0; i<10000; i++) {
        //generate a new particle if necessary
        // (Geant3 emulation)
        if (newParticle) {
            px = gRandom->Gaus(0,.02);
            py = gRandom->Gaus(0,.02);
            pz = gRandom->Gaus(0,.02);
            p = TMath::Sqrt(px*px+py*py+pz*pz);
            charge = 1; if (gRandom->Rndm() < 0.5) charge = -1;
            gstep.pid += 1;
            gstep.vect[0] = 0;
            gstep.vect[1] = 0;
            gstep.vect[2] = 0;
            gstep.vect[3] = px/p;
            gstep.vect[4] = py/p;
            gstep.vect[5] = pz/p;
            gstep.vect[6] = charge*TMath::Sqrt(p*p + mass*mass);
            gstep.getot = TMath::Sqrt(p*p + mass*mass);
            gstep.gekin = gstep.getot - mass;
            newParticle = kFALSE;
        }
        // continued …
    }
    // make one step
    helixStep(gstep.step, gstep.vect, vout);
    //apply energy loss
    gstep.destep = gstep.step*gRandom->Gaus(0.0002,0.00001);
    gstep.gekin -= gstep.destep;
    gstep.getot = gstep.gekin + mass;
    gstep.vect[6]= charge*TMath::Sqrt(gstep.getot*gstep.getot - mass*mass);
    gstep.vect[0] = vout[0];
    gstep.vect[1] = vout[1];
    gstep.vect[2] = vout[2];
    gstep.vect[3] = vout[3];
    gstep.vect[4] = vout[4];
    gstep.vect[5] = vout[5];
    gstep.nmec = (Int_t)(5*gRandom->Rndm());
    for (Int_t l=0;l<gstep.nmec;l++) gstep.lmec[l] = l;
    if (gstep.gekin < 0.001) newParticle = kTRUE;
    if (TMath::Abs(gstep.vect[2]) > 30)
        newParticle = kTRUE;
    }
    // save the Tree header. The file will be automatically
    // closed when going out of the function scope
    t2.Write();
}
```

Adding a Branch with a Fixed Length Array

At first, we create a tree and create branches for a subset of variables in the C structure `Gctrak_t`. Then we add several types of branches.

The first branch reads seven floating point values beginning at the address of `gstep.vect`. You do not need to specify `&gstep.vect`, because in C and C++ the array variable holds the address of the first element.

```c
t2.Branch("vect",gstep.vect,"vect[7]/F");
t2.Branch("getot",gstep.getot,"getot/F");
t2.Branch("gekin",gstep.gekin,"gekin/F");
```

Adding a Branch with a Variable Length Array

The next two branches are dependent on each other. The first holds the length of the variable length array and the second holds the variable length array.

The `nmec` branch reads `nmec` number of integers beginning at the address `gstep.destep`.

```c
t2.Branch("nmec",&gstep.nmec,"nmec/I");
t2.Branch("lmec",gstep.lmec,"lmec[nnec/I]/I");
```
The variable \texttt{nmec} is a random number and is reset for each entry.

\begin{verbatim}
gstep.nmec = (Int_t)(5*gRandom->Rndm());
\end{verbatim}

\textbf{Filling the Tree}

In this emulation of Geant3, we generate and transport particles in a magnetic field and store the particle parameters at each tracking step in a ROOT tree.

\textbf{Analysis}

In this analysis we do not read the entire entry, we only read one branch. First we set the address for the branch to the file \texttt{dstep}, then we use the \texttt{TBranch::GetEntry} method.

Then we fill a histogram with the \texttt{dstep} branch entries, draw it and fit it with a gaussian.

In addition we draw the particle's path using the three values in the vector. Here we use the \texttt{TTree::Draw} method. It automatically creates a histogram and plots the 3 expressions (see Using Trees in Analysis).

\begin{verbatim}
void tree2r()
{
    // read the Tree generated by tree2w and fill one histogram
    // we are only interested by the destep branch.
    // note that we use "new" to create the TFile and TTree objects
    // because we want to keep these objects alive when we leave
    // this function:
    TFile *f = new TFile("tree2.root");
    TTree *t2 = (TTree*)f->Get("t2");
    static Float_t destep;
    TBranch *b_destep = t2->GetBranch("destep");
    b_destep->SetAddress(&destep);
    //create one histogram
    TH1F *hdestep = new TH1F("hdestep","destep in Mev",100,1e-5,3e-5);
    //read only the destep branch for all entries
    Int_t nentries = (Int_t)t2->GetEntries();
    for (Int_t i=0;i<nentries;i++) {
        b_destep->GetEntry(i);
        // fill the histogram with the destep entry
        hdestep->Fill(destep);
    }
    // we do not close the file.
    // We want to keep the generated histograms
    // We fill a 3-d scatter plot with the particle
    // step coordinates
    TCanvas *c1 = new TCanvas("c1","c1",600,800);
    c1->SetFillColor(45);
    hdestep->Fit("gaus");
    c1->cd(2);
    gPad->SetFillColor(37);
    t2->SetMarkerColor(kRed);
    t2->Draw("vect[0]:vect[1]:vect[2]");
    if (gROOT->IsBatch()) return;
    // invoke the x3d viewer
    gPad->x3d();
}
\end{verbatim}
Example 3: Adding Friends to Trees

In this example we will show how to extend a tree with a branch from another tree with the Friends feature.

Adding a Branch to an Existing Tree

You may want to add a branch to an existing tree. For example, if one variable in the tree was computed with a certain algorithm, you may want to try another algorithm and compare the results.

One solution is to add a new branch, fill it, and save the tree. The code below adds a simple branch to an existing tree.

Note the `kOverwrite` option in the `Write` method, it overwrites the existing tree. If it is not specified, two copies of the tree headers are saved.

```cpp
void tree3AddBranch(){
  TFile f("tree3.root","update");
  Float_t new_v;
  TTree *t3 = (TTree*)f->Get("t3");
  TBranch *newBranch = t3->Branch("new_v", &new_v, "new_v/F");
  //read the number of entries in the t3
  Int_t nentries = (Int_t)t3->GetEntries();
  for (Int_t i = 0; i < nentries; i++){
    new_v= gRandom->Gaus(0,1);
    newBranch->Fill();
  }
  // save only the new version of the tree
  t3->Write(""," TObject::kOverwrite");
}
```

Adding a branch is often not possible because the tree is in a read-only file and you do not have permission to save the modified tree with the new branch. Even if you do have the permission, you risk losing the original tree with an unsuccessful attempt to save the modification. Since trees are usually large, adding a branch could extend it over the 2GB limit. In this case, the attempt to write the tree fails, and the original data may also be corrupted.

In addition, adding a branch to a tree enlarges the tree and increases the amount of memory needed to read an entry, and therefore decreases the performance.

For these reasons, ROOT offers the concept of friends for trees (and chains). We encourage you to use `TTree::AddFriend` rather than adding a branch manually.

### TTree::AddFriend

A tree keeps a list of friends. In the context of a tree (or a chain), friendship means unrestricted access to the friends data. In this way it is much like adding another branch to the tree without taking the risk of damaging it. To add a friend to the list, you can use the `TTree::AddFriend` method.

The TTree (tree) below has two friends (ft1 and ft2) and now has access to the variables a,b,c,i,j,k,l and m.

The `AddFriend` method has two parameters, the first is the tree name and the second is the name of the ROOT file where the friend tree is saved. `AddFriend` automatically opens the friend file. If no file name is given, the tree called ft1 is assumed to be in the same file as the original tree.

```cpp
    tree.AddFriend("ft1","friendfile1.root");
```

If the friend tree has the same name as the original tree, you can give it an alias in the context of the friendship:

```cpp
    tree.AddFriend("tree = tree","friendfile1.root");
```

Once the tree has friends, we can use `TTree::Draw` as if the friend's variables were in the original tree. To specify which tree to use in the `Draw` method, use the syntax:

```cpp
<treeName>.<branchname>.<varname>
```

If the `variablename` is enough to uniquely identify the variable, you can leave out the tree and/or branch name.

For example, these commands generate a 3-d scatter plot of variable "var" in the TTree `tree` versus variable v1 in TTree `ft1` versus variable v2 in TTree `ft2`.

```cpp
    tree.AddFriend("ft1","friendfile1.root");
    tree.AddFriend("ft2","friendfile2.root");
    tree.Draw("var:ft1.v1:ft2.v2");
```

The picture illustrates the access of the tree and its friends with a `Draw` command.

When `AddFriend` is called, the ROOT file is automatically opened and the friend tree (ft1) header is read into memory. The new friend (ft1) is added to the list of friends of tree.

The number of entries in the friend must be equal or greater to the number of entries of the original tree. If the friend tree has fewer entries a warning is given and the missing entries are not included in the histogram.
To retrieve the list of friends from a tree use TTree::GetListOfFriends.

When the tree is written to file (TTree::Write), the friends list is saved with it. And when the tree is retrieved, the trees on the friends list are also retrieved and the friendship restored.

When a tree is deleted, the elements of the friend list are also deleted.

It is possible to declare a friend tree that has the same internal structure (same branches and leaves) as the original tree, and compare the same values by specifying the tree.

```
void tree3w() {
// Example of a Tree where branches are variable length
// arrays
// A second Tree is created and filled in parallel.
// Run this script with
//   .x tree3.C

// In the function treeer, the first Tree is open.
// The second Tree is declared friend of the first tree.
// TTree::Draw is called with variables from both Trees.

const Int_t kMaxTrack = 500;
Int_t ntrack;
Int_t stat[kMaxTrack];
Int_t sign[kMaxTrack];
Float_t px[kMaxTrack];
Float_t py[kMaxTrack];
Float_t pz[kMaxTrack];
Float_t zv[kMaxTrack];
Float_t chi2[kMaxTrack];
Double_t sumstat;

// create the first root file with a tree
TFile f("tree3.root", "recreate");
TTree *t3 = new TTree("t3", "Reconst ntuple");
t3->Branch("ntrack", &ntrack, "ntrack/I");
t3->Branch("stat", stat, "stat[ntrack]/I");
t3->Branch("sign", sign, "sign[ntrack]/I");
t3->Branch("px", px, "px[ntrack]/F");
t3->Branch("py", py, "py[ntrack]/F");
t3->Branch("pz", pz, "pz[ntrack]/F");
t3->Branch("zv", zv, "zv[ntrack]/F");
t3->Branch("chi2", chi2, "chi2[ntrack]/F");

// create the second root file with a different tree
TFile fr("tree3f.root", "recreate");
TTree *t3f = new TTree("t3f", "a friend Tree");
t3f->Branch("ntrack", &ntrack, "ntrack/I");
t3f->Branch("sumstat", &sumstat, "sumstat/D");
t3f->Branch("pt", &pt, "pt[ntrack]/F");

// Fill the trees
for (Int_t i=0;i<1000;i++) {
  Int_t nt = gRandom->Rndm()*(kMaxTrack-1);
  ntrack = nt;
  sumstat = 0;
  // set the values in each track
  for (Int_t n=0;n<nt;n++) {
    stat[n] = n%3;
    sign[n] = i%2;
    px[n] = gRandom->Gaus(0,1);
    py[n] = gRandom->Gaus(0,2);
    pz[n] = gRandom->Gaus(10,5);
    zv[n] = gRandom->Gaus(100,2);
    chi2[n] = gRandom->Gaus(0,.01);
    sumstat += chi2[n];
    pt[n] = TMath::Sqrt(px[n]*px[n] + py[n]*py[n]);
  }
  t3->Fill();
  t3f->Fill();
}

// Write the two files
f.cd();
t3->Print();
f.cd();
fr.cd();
t3f->Write();
fr.cd();
}

// Function to read the two files and add the friend
void tree3r() {
  TFile *f = new TFile("tree3.root");
  TTree *t3 = (TTree*)f->Get("t3");
  // Add the second tree to the first tree as a friend
  t3->AddFriend("t3f", "tree3f.root");
  // Draw pz which is in the first tree and use pt
  // in the condition. pt is in the friend tree.
  t3->Draw("pz","pt>3");
}

// This is executed when typing .x tree3.C
void tree3() {
tree3w();
tree3r();
}
```
Example 4: A Tree with an Event Class

This example is a simplified version of $ROOTSYS/test/MainEvent.cxx and where Event objects are saved in a tree. The full definition of Event is in $ROOTSYS/test/Event.h. To execute this macro, you will need the library $ROOTSYS/test/libEvent.so. If it does not exist you can build the test directory applications by following the instruction in the $ROOTSYS/test/README file.

In this example we will show

• the difference in splitting or not splitting a branch
• how to read selected branches of the tree,
• how to print a selected entry

The Event Class

Event is a descendent of TObject. As such it inherits the data members of TObject and its methods such as Dump() and Inspect() and Write(). Also, because it inherits from TObject it can be a member of a collection.

To summarize, the advantages of inheriting from a TObject are:

• Inherit the Write, Inspect, and Dump methods
• Enables a class to be a member of a ROOT collection
• Enables RTTI

Below is the list of the Event data members. It contains a character array, several integers, a floating point number, and an EventHeader object. The EventHeader class is described in the following paragraph. Event also has two pointers, one to a TClonesArray of tracks and one to a histogram. The string "->" in the comment field of the members *fTracks and *fH instructs the automatic Streamer to assume that the objects *fTracks and *fH are never null pointers and that fTracks->Streamer can be used instead of the more time consuming form R__b << fTracks.

```
class Event : public TObject {
private:
  char           fType[20];
  Int_t          fNtrack;
  Int_t          fNseg;
  Int_t          fNvertex;
  UInt_t         fFlag;
  Float_t        fTemperature;
  EventHeader    fEvtHdr;
  TClonesArray  *fTracks;  //->
  Float_t        fMeasures[10];
  TH1F           *fHist;
  TClonesArray  *fgTracks;
  TH1F           *fgHist;
  TH1F           *fHist;
  Int_t          fMeasures[10];
  Float_t        fMatrix[4][4];
  Float_t        *fClosestDistance;  //fNvertex
  static TClonesArray *fgTracks;
  static TH1F    *fgHist;
// ... list of methods
- ClassDef(Event,1)  //Event structure
};
```

The EventHeader Class

The EventHeader class (also defined in Event.h) does not inherit from TObject. Beginning with ROOT 3.0, an object can be placed on a branch even though it does not inherit from TObject. In previous releases branches were restricted to objects inheriting from the TObject. However, it has always been possible to write a class not inheriting from TObject to a tree by encapsulating it in a TObject descendent class as is the case in EventHeader and Event.

```
class EventHeader {
private:
  Int_t   fEvtNum;
  Int_t   fRun;
  Int_t   fDate;
// ... list of methods
- ClassDef(EventHeader,1)  //Event Header
};
```

The Track Class

The Track class descends from TObject since tracks are in a TClonesArray (i.e. a ROOT collection class) and contains a selection of basic types and an array of vertices. Its TObject inheritance, enables Track to be in a collection, and in Event is a TClonesArray of Tracks.

```
class Track : public TObject {
private:
  Float_t      fPx;            //X component of the momentum
  Float_t      fPy;            //Y component of the momentum
  Float_t      fPz;            //Z component of the momentum
  Float_t      fRandom;        //A random track quantity
  Float_t      fMass2;         //The mass square of this particle
  Float_t      fBx;            //X intercept at the vertex
  Float_t      fBy;            //Y intercept at the vertex
  Float_t      fMeanCharge;    //Mean charge deposition of all hits
  Float_t      fXfirst;        //X coordinate of the first point
  Float_t      fYfirst;        //Y coordinate of the first point
  Float_t      fXlast;         //X coordinate of the last point
  Float_t      fYlast;         //Y coordinate of the last point
  Float_t      fCharge;        //Charge of this track
  Int_t        fNpoint;        //Number of points for this track
  Short_t      fValid;         //Validity criterion
// method definitions ...
- ClassDef(Track,1)  //A track segment
};
```
Writing the Tree

We create a simple tree with two branches both holding Event objects. One is split and the other is not. We also create a pointer to an Event object (event).

```c
void tree4w()
{
    // check to see if the event class is in the dictionary
    // if it is not load the definition in libEvent.so
    if (!TClassTable::GetDict("Event")) {
        gSystem->Load("$ROOTSYS/test/libEvent.so");
    }

    // Create a Tree file tree4.root
    TFile f("tree4.root","RECREATE");

    // Create a ROOT Tree
    TTree t4("t4","A Tree with Events");

    // Create a pointer to an Event object
    Event *event = new Event();

    // Create two branches, split one.
    t4.Branch("event_branch", "Event", &event, 16000, 2);
    t4.Branch("event_not_split", "Event", &event, 16000, 0);

    // a local variable for the event type
    char etype[20];

    // Fill the tree
    for (Int_t ev = 0; ev < 100; ev++) {
        Float_t sigmat, sigmas;
        gRandom->Rannor(sigmat, sigmas);
        Int_t ntrack = Int_t(600 + 600 * sigmat / 120.);
        Float_t random = gRandom->Rndm(1);
        sprintf(etype,"type%d", ev % 5);
        event->SetType(etype);
        event->SetHeader(ev, 200, 960312, random);
        event->SetNseg(Int_t(10 * ntrack + 20 * sigmas));
        event->SetNvertex(Int_t(1 + 20 * gRandom->Rndm()));
        event->SetFlag(UInt_t(random + 0.5));
        event->SetTemperature(random + 20.);
        for (UChar_t m = 0; m < 10; m++) {
            event->SetMeasure(m, Int_t(gRandom->Gaus(m, m + 1)));}
        }

    //.. continued
}
```

Reading the Tree

First, we check if the shared library with the class definitions is loaded. If not we load it.

Then we read two branches, one for the number of tracks and one for the entire event. We check the number of tracks first, and if it meets our condition we read the entire event. We show the first entry that meets the condition.

```c
void tree4r()
{
    // check to see if the event class is in the dictionary
    // if it is not load the definition in libEvent.so
    if (!TClassTable::GetDict("Event")) {
        gSystem->Load("$ROOTSYS/test/libEvent.so");
    }

    // read the tree generated with tree4w
    // note that we use "new" to create the TFile and
    // TTree objects, because we want to keep these
    // objects alive when we leave this function.
    TFile *f = new TFile("tree4.root");
    TTree *t4 = (TTree*)f->Get("t4");

    // create a pointer to an event object. This will be used
    // to read the branch values.
    Event *event = new Event();

    // get two branches and set the branch address
    TBranch *ntrack = t4->GetBranch("fNtrack");
    TBranch *branch = t4->GetBranch("event_split");
    branch->SetAddress(&event);
    Int_t nevent = t4->GetEntries();
    Int_t nselected = 0;
    Int_t nb = 0;

    //.. continued ...
```
for (Int_t i=0;i<nevent;i++) {
  //read branch *fNtrack*only
  bntrack->GetEntry(i);
  //reject events with more than 587 tracks
  if (event->GetNtrack() > 587) continue;
  //read complete accepted event in memory
  nb += t4->GetEntry(i);
  nselected++;
  //print the first accepted event
  if (nselected == 1) t4->Show();
  //clear tracks array
  event->Clear();
}
if (gROOT->IsBatch()) return;
new TBrowser();
t4->StartViewer();
}

Now, let's see what the tree looks like in the tree viewer.

Trees in Analysis

The methods TTree::Draw, TTree::MakeClass, and TTree::MakeSelector are available for data analysis using trees.

The TTree::Draw method is a powerful yet simple way to look and draw the trees contents. It enables you to plot a variable (a leaf) with just one line of code. However, the Draw method falls short once you want to look at each entry and design more sophisticated acceptance criteria for your analysis. For these cases, you can use TTree::MakeClass. It creates a class that loops over the trees entries one by one. You can then expand it to do the logic of your analysis.

The TTree::MakeSelector is the recommended method for ROOT data analysis. It is especially important for large data set in a parallel processing configuration where the analysis is distributed over several processors and you can specify which entries to send to each processors. With MakeClass the user has control over the event loop, with MakeSelector the tree is in control of the event loop.

Simple Analysis using TTree::Draw

We will use the tree in staff.root which was made by the macro in $ROOTSYS/tutorials/staff.C.

First, open the file and lists its contents.

You can see the two branches in the tree in the left panel: the event_branch is split and hence expands when clicked on. The other branch event_not_split is not expandable and we can not browse the data members.

The TClonesArray of tracks fTracks is also split because we set the split level to 2.

The output on the command line is the result of tree4->Show. It shows the first entry with more than 587 tracks.

TClonesArray of tracks fTracks is also split because we set the split level to 2.
CINT allows us to simply get the object by using it. Here we define a pointer to a TTree object and assign it the value of "tree", the TTree in the file. CINT looks for "tree" and returns it.

To show the different Draw options, we create a canvas with four sub-pads. We will use one sub-pad for each Draw command.

We activate the first pad with the TCanvas::cd statement:

As you can see this call to TTree::Draw has only one parameter. It is a string containing the leaf name.

A histogram is automatically created as a result of a TTree::Draw. The style of the histogram is inherited from the TTree attributes and the current style (gStyle) is ignored. The TTree gets its attributes from the current TStyle at the time it was created. You can call the method TTree::UseCurrentStyle to change to the current style rather than the TTree style (see gStyle, see the Chapter Graphics and Graphic User Interfaces).

In this next segment we activate the second pad and draw a scatter plot variables:

This signature still only has one parameter, but it now has two dimensions separated by a colon ("x:y"). The item to be plotted can be an expression not just a simple variable. In general, this parameter is a string that contains up to three expressions, one for each dimension, separated by a colon ("e1:e2:e3"). A list of examples follows this introduction.

Using Selection with TTree::Draw

Change the active pad to 3, and add a selection to the list of parameters of the draw command.

This will draw the cost vs. age for the entries where the nation is equal to 3. You can use any C++ operator, plus some functions defined in TBranch, in the selection parameter.

The value of the selection is used as a weight when filling the histogram. If the expression includes only Boolean operations as in the example above, the result is 0 or 1. If the result is 0, the histogram is not filled. In general, the expression is:

Selection = "weight *(boolean expression)"

If the Boolean expression evaluates to true, the histogram is filled with a weight. If the weight is not explicitly specified it is assumed to be 1.

For example, this selection will add 1 to the histogram if x is less than y and the square root of z is less than 3.2.

On the other hand, this selection will add x+y to the histogram if the square root of z is larger than 3.2.

The Draw method has its own parser, and it only looks in the current tree for variables. This means that any variable used in the selection must be defined in the tree. You cannot use an arbitrary global variable in the TTree::Draw method.

Using TCut Objects in TTree::Draw

The TTree::Draw method also accepts TCut objects. A TCut is a specialized string object used for TTree selections. A TCut object has a name and a title. It does not have any data members in addition to what it inherits from TBranch. A TCut object inherits from TBranch.

Operators +=, +=, &, |, &|, || are overloaded, here are some examples:

The Draw method has its own parser, and it only looks in the current tree for variables. This means that any variable used in the selection must be defined in the tree. You cannot use an arbitrary global variable in the TTree::Draw method.

Using TCut Objects in TTree::Draw

The TTree::Draw method also accepts TCut objects. A TCut is a specialized string object used for TTree selections. A TCut object has a name and a title. It does not have any data members in addition to what it inherits from TBranch. A TCut object inherits from TBranch.
Accessing the Histogram in Batch Mode

The `TTree::Draw` method creates a histogram called `htemp` and puts it on the active pad.

In a batch program, the histogram `htemp` created by default, is reachable from the current pad.

```c
// draw the histogram
nt->Draw("x", "cuts");
// get the histogram from the current pad
TH1F htemp = (TH1F*) gPad->GetPrimitive("htemp");
// now we have full use of the histogram
htemp->GetEntries();
```

If you pipe the result of the `TTree::Draw` into a histogram, the histogram is also available in the current directory. You can do:

```c
// Draw the histogram and fill hnew with it
nt->Draw("x>>hnew","cuts");
// get hnew from the current directory
TH1F *hnew = (TH1F*)gDirectory->Get("hnew");
// or get hnew from the current Pad
TH1F *hnew = (TH1F*)gPad->GetPrimitive("hnew");
```

Using Draw Options in `TTree::Draw`

The next parameter is the draw option for the histogram:

```c
root [] myCanvas->cd(4)
root [] MyTree->Draw("cost:age","nation == 3", "surf2");
```

The draw options are the same as for `TH1::Draw`, and they are listed in the section: Draw Options in the chapter on Histograms.

In addition to the draw options defined in `TH1`, there are three more.

The 'prof' and 'profs' that draw a profile histogram (`TProfile`) rather than a regular 2D histogram (`TH2D`) from an expression with two variables. If the expression has three variables, a `TProfile2D` is generated. The 'profs' generates a `TProfile2D` with error on the spread. The 'prof' option generates a `TProfile` with error on the mean.

The "goff" option suppresses generating the graphics.

You can combine the draw options in a list separated by commas. After typing the lines above, you should now have a canvas that looks like this.

Superimposing two Histograms

When superimposing two 2-D histograms inside a script with `TTree::Draw` and using the "same" option, you will need to update the pad between `Draw` commands.

```c
// superimpose two 2D scatter plots
{
  // Create a 2D histogram and fill it with random numbers
  TH2 h2 = new TH2D("h2","2D histo",100,0,70,100,0,20000);
  for (Int_t i = 0; i < 10000; i++)
    h2->Fill(gRandom->Gaus(40,10),gRandom->Gaus(10000,3000));
  // set the color to differentiate it visually
  h2->SetMarkerColor(kGreen);
  h2->Draw();
  // Open the example file and get the tree
  TFile f("staff.root");
  TTree *myTree = (TTree*)f.Get("tree");
  // the update is needed for the next draw command to
  // work properly
  gPad->Update();
  myTree->Draw("cost:age", ",";"same");
}
```

In this example, `h2->Draw` is only adding the object `h2` to the pad’s list of primitives. It does not paint the object on the screen. However, `TTree::Draw` when called with option "same" gets the current pad coordinates to build an intermediate histogram with the right limits. Since nothing has been painted in the pad yet, the pad limits have not been computed. Calling `pad->Update` forces the painting of the pad and allows `TTree::Draw` to compute the right limits for the intermediate histogram.

Setting the Range in `TTree::Draw`

There are two more optional parameters to the `TTree::Draw` method: one is the number of entries and the second one is the entry to start with. For example this command draws 1000 entries starting with entry 100:

```c
myTree->Draw("cost:age", ",","1000,100");
```

`TTree::Draw` Examples

The examples below use the `Event.root` file generated by the `$ROOTSYS/test/Event` executable and the `Event`, `Track`, and `EventHeader` class definitions are in `$ROOTSYS/test/Event.h`.

The commands have been tested on the split levels 0, 1, and 9. Each command is numbered and referenced by the explanations immediately following the examples.
// Data members and methods
1. tree->Draw("fNtrack");
2. tree->Draw("event.GetNtrack()");
3. tree->Draw("GetNtrack()");
4. tree->Draw("fH.fXaxis.fXmax");
5. tree->Draw("fH.fXaxis.GetXmax()");
6. tree->Draw("fH.GetXaxis().fXmax");
7. tree->Draw("GetHistogram().GetXaxis().GetXmax()");

// expressions in the selection parameter
8. tree->Draw("fTracks.fPx","fEvtHdr.fEvtNum%10 == 0");
9. tree->Draw("fPx", "fEvtHdr.fEvtNum%10 == 0");

// Two dimensional arrays
// fMatrix is defined as:
//  Float_t  fMatrix[4][4];   in Event class
10. tree->Draw("fMatrix");
11. tree->Draw("fMatrix[][]");
12. tree->Draw("fMatrix[2][2]");
13. tree->Draw("fMatrix[][0]");
14. tree->Draw("fMatrix[1][]");

// using two arrays
//  Float_t  fVertex[3];     in Track class
15. tree->Draw("fMatrix - fVertex");
16. tree->Draw("fMatrix[2][1] - fVertex[5][1]");
17. tree->Draw("fMatrix[][1] - fVertex[5][1]");
18. tree->Draw("fMatrix[2][] - fVertex[5][]");
19. tree->Draw("fMatrix[1][2] - fVertex[ ][1]");
20. tree->Draw("fMatrix[][2] - fVertex[ ][ ]");
21. tree->Draw("fMatrix[][ ] - fVertex[ ][ ]");

// variable length arrays
22. tree->Draw("fClosestDistance");
23. tree->Draw("fClosestDistance[fNvertex/2]");

// mathematical expressions
24. tree->Draw("sqrt(fPx*fPx + fPy*fPy + fPz*fPz)\)");

// strings
25. tree->Draw("fEvtHdr.fEvtNum","fType=="type1"");
26. tree->Draw("fEvtHdr.fEvtNum","strstr(fType,"1")");

// Where fPoints is defined in the track class:
// Int_t  fPoint;
// Int_t  *fPoints; [fPoint]
27. tree->Draw("fTracks.fPoints");
28. tree->Draw("fTracks.fPoints[]");
29. tree->Draw("fTracks.fPoints[2][]");
30. tree->Draw("fTracks.fPoints[][55]");
31. tree->Draw("fTracks.fPoints[][ ][55]");
32. tree->Draw("fTracks.fPoints[ ][ ]");

// Selections
31. tree->Draw("fValid&0x1", "(fNvertex>10) && (fNseg<=600)")
32. tree->Draw("fPx", "(fBx>.4) || (fBy<=-.4)"");
33. tree->Draw("fPx", "fBx*fBx*(fBx>.4) + fBy*fBy*(fBy<=-.4)"");
34. tree->Draw("fVertex", "fVertex>10")
35. tree->Draw("fPx[600]");
36. tree->Draw("fPx[600]","fNtrack>600")
37. tree->Draw("Nation")
38. tree->Draw("MyByte + 0")

Explanations:
1. tree->Draw("fNtrack"); Fills the histogram with the number of tracks for each entry. fNtrack is a member of event.
2. tree->Draw("event.GetNtrack()"); Same as case 1, but use the method of event to get the number of tracks. When using a method, you can include parameters for the method as long as the parameters are literals.
3. tree->Draw("GetNtrack()"); Same as case 2, the object of the method is not specified. The command uses the first instance of the GetNtrack method found in the objects stored in the tree. We recommend using this shortcut only if the method name is unique.
4. tree->Draw("fH.fXaxis.fXmax"); Draw the data member of a data member. In the tree, each entry has a histogram. This command draws the maximum value of the X-axis for each histogram.
5. tree->Draw("fH.fXaxis.GetXmax()"); Same as case 4, but use the method of a data member.
6. tree->Draw("fH.GetXaxis().fXmax"); Same as case 4, a data member of a data member retrieved by a method.
7. tree->Draw("GetHistogram().GetXaxis().GetXmax()"); Same as case 4, using only methods.
8. tree->Draw("fTracks.fPx","fEvtHdr.fEvtNum%10 == 0")
9. tree->Draw("fPx","fEvtHdr.fEvtNum%10 == 0")
10. tree->Draw("fMatrix");
When the index of the array is left out or when empty brackets are used [], all values of the array are selected.

Draw all values of fMatrix for each entry in the tree. If fMatrix is defined as Float_t fMatrix[4][4], all 16 values are used for each entry.

11. tree->Draw("fMatrix[ ] [ ]");
The same case as 10, all values of fMatrix are drawn for each entry.

12. tree->Draw("fMatrix[2][ ]");
The single element at fMatrix[2][ ] is drawn for each entry.

13. tree->Draw("fMatrix[ ] [0][ ]");
Four elements of fMatrix are used: fMatrix[1][0], fMatrix[2][0], fMatrix[3][0], fMatrix[4][0].

14. tree->Draw("fMatrix[1][ ]");
Four elements of fMatrix are used: fMatrix[1][0], fMatrix[1][1], fMatrix[1][2], fMatrix[1][3].

15. tree->Draw("fMatrix = fVertex");
With two arrays and unspecified element numbers, the number of selected values is the minimum of the first dimension times the minimum of the second dimension. In this case fVertex is also a two dimensional array since it is a data member of the tracks array. If fVertex is defined in the track class as Float_t *fVertex[3], it has 3 x 5 elements. fMatrix has 4 x 4 elements. This case, draws 4 x (the lesser of fNtrack and 4) times 3 (the lesser of 4 and 3), meaning 12 elements per entry. The selected values for each entry are:

- fMatrix[0][0] - fVertex[0][0]
- fMatrix[0][1] - fVertex[0][1]
- fMatrix[0][2] - fVertex[0][2]
- fMatrix[0][3] - fVertex[0][3]
- fMatrix[1][0] - fVertex[1][0]
- fMatrix[1][1] - fVertex[1][1]
- fMatrix[1][2] - fVertex[1][2]
- fMatrix[1][3] - fVertex[1][3]
- fMatrix[2][0] - fVertex[2][0]
- fMatrix[2][1] - fVertex[2][1]
- fMatrix[3][0] - fVertex[3][0]
- fMatrix[3][1] - fVertex[3][1]
- fMatrix[3][2] - fVertex[3][2]
- fMatrix[3][3] - fVertex[3][3]

16. tree->Draw("fMatrix[2][1] - fVertex[5][1]");
This command selects one value per entry.

17. tree->Draw("fMatrix[ ] [1] - fVertex[5][1]");
The first dimension of the array is taken by the fMatrix.

- fMatrix[0][1] - fVertex[5][1]
- fMatrix[1][1] - fVertex[5][1]
- fMatrix[2][1] - fVertex[5][1]
- fMatrix[3][1] - fVertex[5][1]

18. tree->Draw("fMatrix[2][ ] - fVertex[5][ ]");
The first dimension minimum is 2, and the second dimension minimum is 3 (from fVertex). Three values are selected from each entry:

- fMatrix[2][0] - fVertex[5][0]
- fMatrix[2][1] - fVertex[5][1]

19. tree->Draw("fMatrix[ ] [2] - fVertex[ ] [1]"*
This is similar to case 18. Four values are selected from each entry:

- fMatrix[0][2] - fVertex[0][1]
- fMatrix[1][2] - fVertex[1][1]
- fMatrix[3][2] - fVertex[3][1]

20. tree->Draw("fMatrix[ ] [2] - fVertex[ ] [ ]")
This is similar to case 19. Twelve values are selected (4x3) from each entry:

- fMatrix[0][2] - fVertex[0][0]
- fMatrix[1][2] - fVertex[0][1]
- fMatrix[2][2] - fVertex[1][0]
- fMatrix[3][2] - fVertex[1][1]
- fMatrix[0][2] - fVertex[2][0]
- fMatrix[1][2] - fVertex[2][1]
- fMatrix[3][2] - fVertex[2][3]
- fMatrix[0][3] - fVertex[3][0]
- fMatrix[1][3] - fVertex[3][1]
- fMatrix[3][3] - fVertex[3][3]

21. tree->Draw("fMatrix[ ] [ ] - fVertex[ ] [ ]")
This is the same as case 15. The first dimension minimum is 4 (from fMatrix), and the second dimension minimum is 3 (from fVertex). Twelve values are selected from each entry.

22. tree->Draw("fClosestDistance")
This event data member fClosestDistance is a variable length array: Float_t *fClosestDistance; // [fNvertex].
This command selects all elements, but the number per entry depends on the number of vertices of that entry.

23. tree->Draw("fClosestDistance[fNvertex/2]")
With this command the element at fNvertex/2 of the fClosestDistance array is selected. Only one per entry is selected.

24. tree->Draw("sqrt(fPx*fPx + fPy*fPy + fPz*fPz)")
This command shows the use of a mathematical expression. It draws the square root of the sum of the product.

25. tree->Draw("fEvtHdr.fEvtNum","fType=="type1" ")
You can compare strings, using the symbols == and !=, in the first two parameters of the Draw command (TTreeFormula). In this case, the event number for 'type1' events is plotted.

26. tree->Draw("fEvtHdr.fEvtNum","strstr(fType,"\"type1\"\")")
To compare strings, you can also use strstr. In this case, events having a 'T' in fType are selected.

27. tree->Draw("fTracks.fPoints")
If fPoints is a data member of the Track class declared as:
Int_t *fPoint;
Int_t *fPoints; [fNpoint]

fMatrix[2][2] - fVertex[5][2]
The size of the array \texttt{fPoints} varies with each track of each event. This command draws all the value in the \texttt{fPoints} arrays.

28. \texttt{tree->Draw("fTracks.fPoints\ - fTracks.fPoints[fAvgPoints]");}

When \texttt{fAvgPoints} is a data member of the \texttt{Event} class, this example selects:

\begin{verbatim}
  fTracks[0].fPoints[0] - fTracks[0].fPoint[fAvgPoints]
fTracks[0].fPoints[1] - fTracks[0].fPoint[fAvgPoints]
fTracks[0].fPoints[2] - fTracks[0].fPoint[fAvgPoints]
fTracks[0].fPoints[3] - fTracks[0].fPoint[fAvgPoints]
fTracks[0].fPoints[4] - fTracks[0].fPoint[fAvgPoints]
... 
fTracks[0].fPoints[max0] - fTracks[0].fPoint[fAvgPoints]
fTracks[1].fPoints[0] - fTracks[1].fPoint[fAvgPoints]
fTracks[1].fPoints[1] - fTracks[1].fPoint[fAvgPoints]
... 
fTracks[1].fPoints[max1] - fTracks[1].fPoint[fAvgPoints]
fTracks[1].fPoints[0] - fTracks[1].fPoint[fAvgPoints]
fTracks[1].fPoints[1] - fTracks[1].fPoint[fAvgPoints]
... 
fTracks[fNtrack-1].fPoints[0] - fTracks[fNtrack-1].fPoint[fAvgPoints]
fTracks[fNtrack-1].fPoints[1] - fTracks[fNtrack-1].fPoint[fAvgPoints]
... 
fTracks[fNtrack-1].fPoints[maxn] - fTracks[fNtrack-1].fPoint[fAvgPoints]
\end{verbatim}

Where max0, max1, ..., max n is the size of the \texttt{fPoints} array for the respective track.

29. \texttt{tree->Draw("fTracks.fPoints[2]-fTracks.fPoints[55]");}

For each event, this expression is selected:

\begin{verbatim}
  fTracks[2].fPoints[0] - fTracks[0].fPoints[55]
fTracks[2].fPoints[1] - fTracks[0].fPoints[55]
... 
fTracks[2].fPoints[max] - fTracks[max].fPoints[55]
\end{verbatim}

where max is the minimum of \texttt{fNtrack} and \texttt{fTracks[2].fNpoint}.

30. \texttt{tree->Draw("fTracks.fPoints[]\[fNtrack\]");}

For each event and each track, this expression is selected. It is the difference between \texttt{fPoints} and \texttt{fVertex}. The number of elements used for each track is the minimum of \texttt{fNpoint} and 3 (the size of the \texttt{fVertex} array).

\begin{verbatim}
  fTracks[0].fPoints[0] - fTracks[0].fVertex[0]
fTracks[0].fPoints[1] - fTracks[0].fVertex[1]
fTracks[0].fPoints[2] - fTracks[0].fVertex[2]
... 
\end{verbatim}

31. \texttt{tree->Draw("fValid&0x1", "(fNvertex>10) && (fNseg<=6000)"})*

You can use bit patterns (\&, |,<<) or Boolean operation.

32. \texttt{tree->Draw("fPx","(fBx>.4) || (fBy<=-.4)"};

33. \texttt{tree->Draw("fPx","fBx*fBx*(fBx>.4) + fBy*fBy*(fBy<=-.4)"};

The selection argument is used as a weight. The expression returns a multiplier and in case of a Boolean the multiplier is either 0 (for false) or 1 (for true). The first command draws \texttt{fPx} for the range between 0.4 and -0.4, the second command draws \texttt{fPx} for the same range, but adds a weight using the result of the second expression.

34. \texttt{tree->Draw("fVertex","fVertex>10")}

When using arrays in the selection and the expression, the selection is applied to each element of the array.

\begin{verbatim}
  if (fVertex[0]>10) fVertex[0]
  if (fVertex[1]>10) fVertex[1]
\end{verbatim}

36. \texttt{tree->Draw("fPx[600]","fNtrack > 600")}

When using a specific element for a variable length array the entries with less elements are ignored. Thus these two commands are equivalent.

37. \texttt{tree->Draw("Nation")}

\texttt{Nation} is a \texttt{char*} branch. When drawing a \texttt{char*} it will plot an alphanumeric histogram, of the different value of the string \texttt{Nation}. The axis will have the \texttt{Nation} values (see Alphanumeric Histograms in the Histogram chapter).

38. \texttt{tree->Draw("MyChar +0")}

If you want to plot a \texttt{char*} variable as a byte rather than a string, you can use the syntax above.
Creating an Event List

The `TTree::Draw` method can also be used to build a list of the entries. When the first argument is preceded by `>>` ROOT knows that this command is not intended to draw anything, but to save the entries in a list with the name given by the first argument. The resulting list is a `TEventList`, and is added to the objects in the current directory.

For example, to create a `TEventList` of all entries with more than 600 tracks:

```cpp
root [] TFile *f = new TFile("Event.root")
root [] T->Draw(">> myList", " fNtrack > 600")
```

This list contains the entry number of all entries with more than 600 tracks. To see the entry numbers use the `Print("all")` command.

```cpp
root [] myList->Print("all")
```

When using the `>>` whatever was in the `TEventList` is overwritten. The `TEventList` can be grown by using the `>>+` syntax.

For example to add the entries, with exactly 600 tracks:

```cpp
root [] T->Draw(">>+ myList", " fNtrack == 600")
```

This command does not add any new entries to the list because all entries with more than 610 tracks have already been found by the previous command for entries with more than 600 tracks.

Using an Event List

The `TEventList` can be used to limit the `TTree` to the events in the list. The `SetEventList` method tells the tree to use the event list and hence limits all subsequent `TTree` methods to the entries in the list. In this example, we create a list with all entries with more than 600 tracks and then set it so the Tree will use this list. To reset the `TTree` to use all events use `SetEventList(0)`.

1) Let's look at an example. First, open the file and draw the `fNtrack`.

```cpp
root [] TFile *f = new TFile("Event.root")
root [] T->Draw("fNtrack ")
```

2) Now, put the entries with over 600 tracks into a `TEventList` called `myList`. We get the list from the current directory and assign it to a variable.

```cpp
root [] TFile *f = new TFile("Event.root")
root [] T->Draw("fNtrack ")
```

Using an Event List

The `TEventList` can be used to limit the `TTree` to the events in the list. The `SetEventList` method tells the tree to use the event list and hence limits all subsequent `TTree` methods to the entries in the list. In this example, we create a list with all entries with more than 600 tracks and then set it so the Tree will use this list. To reset the `TTree` to use all events use `SetEventList(0)`.

1) Let's look at an example. First, open the file and draw the `fNtrack`.

```cpp
root [] TFile *f = new TFile("Event.root")
root [] T->Draw("fNtrack ")
```

Filling a Histogram

The `TTree::Draw` method can also be used to fill a specific histogram. The syntax is:

```cpp
root [] TFile *f = new TFile("Event.root")
root [] T->Draw("fNtrack >> myHisto")
root [] myHisto->Print()
```

As we can see, this created a `TH1` called `myHisto`. If you want to append more entries to the histogram, you can use this syntax:

```cpp
root [] T->Draw("fNtrack >>+ myHisto")
```

If you do not create a histogram ahead of time, ROOT will create one at the time of the Draw command (as is the case above). If you would like to draw the variable into a specific histogram where you, for example, set the range and bin number, you can define the histogram ahead of time and use it in the Draw command. The histogram has to be in the same directory as the tree.

```cpp
TH1 *h1 = new TH1("h1","h1",50, 0., 150.);
root [] T -> Draw("fNtrack>> h1");
```
the method TTree::UseCurrentStyle to change the histogram to use the current style (gStyle, see the Chapter Graphics and Graphic User Interfaces).

The binning of the newly created histogram can be specified in two ways. You can set a defaults in the .rootrc file and/or you can add the binning information in the TTree::Draw command.

To set number of bins default for the 1-d, 2-d, 3-d histograms can be specified in the .rootrc file via the environment variables, e.g.:

```
# default binnings
Hist.Binning.1D.x: 100
Hist.Binning.2D.x: 40
Hist.Binning.2D.y: 40
Hist.Binning.2D.Prof: 100
Hist.Binning.3D.x: 20
Hist.Binning.3D.y: 20
Hist.Binning.3D.z: 20
Hist.Binning.3D.Profx: 100
Hist.Binning.3D.Profy: 100
```

To set the number of bins for a specific histogram when using TTree::Draw, add up to nine numbers following the histogram name. The numbers meaning is:

1 - bins in x-direction
2 - lower limit in x-direction
3 - upper limit in x-direction
4-6 same for y-direction
7-9 same for z-direction

When a bin number is specified, the value becomes the default. Any of the numbers can be skipped. For example:

```
tree.Draw("sqrt(x)>>hsqrt(500,10,20);"
// plot sqrt(x) between 10 and 20 using 500 bins
```

When the name is followed by binning information, appending the histogram with a "+", will not reset hsqrt, but will continue to fill it.

```
tree.Draw("sqrt(x)>>hsqrt","y>0");
```

This works for 1-D, 2-D and 3-D histograms.

### Projecting a Histogram

If you would like to fill a histogram, but not draw it you can use the TTree::Project() method.

### Making a Profile Histogram

In case of a two dimensional expression, you can generate a TProfile histogram instead of a two dimensional histogram by specifying the 'prof' or 'profs' option. The prof option is automatically selected when the output is redirected into a TProfile. For example y:x:prof where prof is an existing TProfile histogram.

### Tree Information

Once we have drawn a tree, we can get information about the tree. These are the methods used to get information from a drawn tree:

- GetSelectedRows: Returns the number of entries accepted by the selection expression. In case where no selection was specified, it returns the number of entries processed.
- GetV1: Returns a pointer to the float array of the first variable.
- GetV2: Returns a pointer to the float array of second variable.
- GetV3: Returns a pointer to the float array of third variable.
- GetW: Returns a pointer to the float array of Weights where the weight equals the result of the selection expression.

To read the drawn values of fNtrack into an array, and loop through the entries follow the lines below. First, open the file and draw the fNtrack variable:

```
root [] TFile *f = new TFile("Event.root")
root [] T->Draw("fNtrack")
```

Then declare a pointer to a float and use the GetV1 method to retrieve the first dimension of the tree. In this example we only drew one dimension (fNtrack) if we had drawn two, we could use GetV2 to get the second one.

```
root [] Float_t *a
root [] a = T->GetV1()
```

Loop through the first 10 entries and print the values of fNtrack:

```
root [] for (int i = 0; i < 10; i++) cout<<a[i]<< " 
root [] cout << endl; // need an endl to see the values
```

By default, TTree::Draw creates these arrays with fEstimate words where fEstimate can be set via TTree::SetEstimate. If you have more entries than fEstimate only the first fEstimate selected entries will be stored in the arrays. The arrays are used as buffers. When fEstimate entries have been processed, ROOT scans the buffers to compute the minimum and maximum of each coordinate and creates the corresponding histograms.

You can use these lines to read all entries into these arrays:
Obviously, this will not work if the number of entries is very large.
This technique is useful in several cases, for example if you want to draw a

graph connecting all the x,y (or z) points. Note that you may have a tree
(or chain) with 1 billion entries, but only a few may survive the cuts and will fit
without problems in these arrays.

Using TTree::MakeClass

The TTree::Draw method is convenient and easy to use, however it falls
short if you need to do some programming with the variable.

For example, for plotting the masses of all oppositely changed pairs of tracks,
you would need to write a program that loops over all events, finds all pairs of
tracks, and calculates the required quantities. We have shown how to retrieve
the data arrays from the branches of the tree in the previous section, and you
could just write that program from scratch. Since this is a very common task,
ROOT provides a utility that generates a skeleton class designed to loop over
the entries of the tree. This is the TTree::MakeClass method

We will now go through the steps of using MakeClass with a simplified
example. The methods used here obviously work for much more complex
event loop calculations.

These are our assumptions:

We would like to do selective plotting and loop through each entry of the tree
and tracks. We chose a simple example: we want to plot fPx
of the first 100
tracks of each entry.

We have a ROOT tree with a branch for each data member in the "Event"
object. To build this file and tree follow the instructions on how to build the
examples in $ROOTSYS/test.

Execute Event and instruct it to split the object with this command (from the
Unix command line).

```bash
$ROOTSYS/test/Event 400 1 2 1
```

This creates an Event.root file with 400 events, compressed, split, and
filled. See $ROOTSYS/test/MainEvent.Cxx for more info.

The person who designed the tree makes a shared library available to you,
which defines the classes needed. In this case, the classes are Event,
EventHeader, and Track and they are defined in the shared library
libEvent.so. The designer also gives you the Event.h file to see the
definition of the classes. You can locate Event.h in $ROOTSYS/test, and if
you have not yet built libEvent.so, please see the instructions of how to
build it. If you have already built it, you can now use it again.

Creating a Class with MakeClass

First, we load the shared library and open Event.root.

```cpp
root [] .L libEvent.so
root [] TFile *f = new TFile("Event.root");
root [] f->ls();
```

From the output of print we can see that the tree has one branch for each
data member of Event, Track, and EventHeader.

Now we can use TTree::MakeClass on our tree "T", MakeClass takes
one parameter, a string containing the name of the class to be made.

In the command below, the name of our class will be "MyClass".

```cpp
root [] T->MakeClass("MyClass");
```

CINT informs us that it has created two files, MyClass.h, which contains the
class definition and MyClass.C, which contains the MyClass::Loop
method. MyClass has more methods than just Loop. The other methods
are: a constructor, a destructor, GetEntry, LoadTree, Notify, and
Show. The implementations of these methods are in the .h file. This division
of methods was done intentionally. The C file is kept as short as possible, and
contains only code that is intended for you to customize. The .h file
contains all the other methods.

To start with, it helps to understand both files, so lets start with MyClass.h
and the class definition:
MyClass.h

```c
class MyClass {
public:
// pointer to the analyzed TTree or TChain
TTree    *fChain;
// current Tree number in a TChain
Int_t    fCurrent;
// Declaration of leaves types
// Declaration of leaves types
UInt_t   fUniqueID;
UInt_t   fBits;
Char_t   fType[20];
Int_t    fNtrack;
Int_t    fNseg;
Int_t    fNvertex;
Float_t  fTemperature;
Int_t    fEvtHdr_fEvtNum;
...
// List of branches
TBranch  *b_fUniqueID;
TBranch  *b_fBits;
TBranch  *b_fType;
TBranch  *b_fNtrack;
TBranch  *b_fNseg;
TBranch  *b_fNvertex;
TBranch  *b_fFlag;
TBranch  *b_fTemperature;
TBranch  *b_fEvtHdr_fEvtNum;
...
MyClass(TTree *tree=0);
~MyClass();
Int_t  Cut(Int_t entry);
Int_t  GetEntry(Int_t entry);
Int_t  LoadTree(Int_t entry);
void   Init(TTree *tree);
void   Loop();
Bool_t Notify();
void   Show(Int_t entry = -1);
};
```

We can see data members in the generated class. The first data member is `fChain`. Once this class is instantiated, `fChain` will point to the original tree or chain this class was made from. In our case, this is "T" in "Event.root". If the class is instantiated with a tree as a parameter to the constructor, `fChain` will point to the tree named in the parameter.

Next is `fCurrent`, which is also a pointer to the current tree/chain. Its role is only relevant when we have multiple trees chained together in a TChain.

The class definition shows us that this tree has one branch and one leaf per data member.

The methods of MyClass are:

- **MyClass(TTree *tree=0);** This constructor has an optional tree for a parameter. If you pass a tree, MyClass will use it rather than the tree from which it was created.
- **MyClass();** This is the destructor, nothing special.
- **Int_t GetEntry(Int_t entry);** This loads the class with the entry specified. Once you have executed GetEntry, the leaf data members in MyClass are set to the values of the entry. For example, GetEntry(12) loads the 13th event into the event data member of MyClass (note that the first entry is 0).
- **Int_t LoadTree(Int_t entry) and void Notify();** These two methods are related to chains. LoadTree will load the tree containing the specified entry from a chain of trees. Notify is called by LoadTree to adjust the branch addresses.
- **void Loop();** This is the skeleton method that loops through each entry of the tree. This is interesting to us, because we will need to customize it for our analysis.

MyClass.C

MyClass::Loop consists of a for-loop calling GetEntry for each entry. In the template, the numbers of bytes are added up, but it does nothing else. If we were to execute it now, there would be no output.

```c
void MyClass::Loop()
{
  if (fChain == 0) return;
  Int_t nentries = fChain->GetEntries();
  Int_t nbytes = 0, nb = 0;
  for (Int_t jentry=0; jentry<nentries;jentry++) {
    Int_t ientry = fChain->GetEntry(jentry);   nbytes += nb;
    // in case of a TChain, ientry is the entry number
    // in the current file
    if (Cut(ientry) < 0) continue;
  }
}
```

At the beginning of the file are instructions about reading selected branches. They are not reprinted here, but please read them from your own file.

### Modifying MyClass::Loop

Lets continue with the goal of going through the first 100 tracks of each entry and plot `Px`. To do this we change the Loop method.

```c
void MyClass::Loop()
{
  if (fChain == 0) return;
  Int_t nentries = fChain->GetEntries();
  Int_t nbytes = 0, nb = 0;
  for (Int_t jentry=0; jentry<nentries; jentry++) {
    Int_t ientry = fChain->GetEntry(jentry);
    // in case of a TChain, ientry is the entry number
    // in the current file
    nb = fChain->GetEntry(jentry);   nbytes += nb;
    if (Cut(jentry) < 0) continue;
  }
}
```

In the for-loop, we need to add another for-loop to go over all the tracks. In the outer for-loop, we get the entry and the number of tracks. In the inner for-loop, we fill the large histogram (myHisto) with all tracks and
the small histogram (smallHisto) with the track if it is in the first 100.

```c
for (Int_t jentry=0; jentry<nentries;jentry++) {
    GetEntry(jentry);
    for (Int_t j = 0; j < 100; j++){
        myHisto->Fill(fTracks_fPx[j]);
        if (j < 100){
            smallHisto->Fill(fTracks_fPx[j]);
        }
    }
}
```

Outside of the for-loop, we draw both histograms on the same canvas.

```c
myHisto->Draw();
smallHisto->Draw("Same");
```

Save these changes to MyClass.C and start a fresh root session. We will now load MyClass and experiment with its methods.

### Loading MyClass

The first step is to load the library and the class file. Then we can instantiate a MyClass object.

```c
root [] .L libEvent.so
root [] .L MyClass.C
root [] MyClass m
```

Now we can get a specific entry and populate the event leaf. In the code snippet below, we get entry 0, and print the number of tracks (594). Then we get entry 1 and print the number of tracks (597).

```c
root [] m.GetEntry(0)
(int)57503
root [] m.fNtrack()
(int)594
root [] m.GetEntry(1)
(int)48045
root [] m.fNtrack()
(int)597
```

Now we can call the `Loop` method, which will build and display the two histograms.

```c
root [] m.Loop()
```

You should now see a canvas that looks like this.

To conclude the discussion on MakeClass let's list the steps that got us here.

- Call `TTree::MakeClass`, which automatically creates a class to loop over the tree.
- Modify the `MyClass::Loop()` method in `MyClass.C` to fit your task.
- Load and instantiate `MyClass`, and run `MyClass::Loop()`.

## Using `TTree::MakeSelector`

With a `TTree` we can make a selector and use it to process a limited set of entries. This is especially important in a parallel processing configuration where the analysis is distributed over several processors and we can specify which entries to send to each processors. The `TTree::Process` method is used to specify the selector and the entries.

Before we can use `TTree::Process` we need to make a selector. We can call the `TTree::MakeSelector` method. It creates two files similar to `TTree::MakeClass`. In the resulting files is a class that is a descendant of `TSelector` and implements the following methods:

- `TSelector::Begin`: This function is called every time a loop over the tree starts. This is a convenient place to create your histograms.
- `TSelector::Notify`: This function is called at the first entry of a new tree in a chain.
- `TSelector::ProcessCut`: This function is called at the beginning of each entry to return a flag true if the entry must be analyzed.
- `TSelector::ProcessFill`: This function is called in the entry loop for all entries accepted by Select.
- `TSelector::Terminate`: This function is called at the end of a loop on a `TTree`. This is a convenient place to draw and fit your histograms.

The `TSelector`, unlike the resulting class from `MakeClass`, separates the processing into a `ProcessCut` and `ProcessFill`, so that we can limit reading the branches to the ones we need.

To create a selector call:

```c
root[] T->MakeSelector("MySelector");
```

Where `T` is the `TTree` and `MySelector` is the name of created class and the name of the .h and .C files.

The resulting `TSelector` is the argument to `TTree::Process`. The argument can be the file name or a pointer to the selector object.

```c
root[] T->Process("MySelector.C",1000,100);
```

This call will interpret the class defined in `MySelector.C` and process 1000 entries beginning with entry 100. The file name can be appended with a "++" to use ACLiC.

```c
root[] T->Process("MySelector.C++",1000,100);
```

When appending a "++", the class will be compiled and dynamically loaded. When it is called again, it recompiles only if the macro `MySelector.C` has changed since it was compiled last. If not it loads the existing library.

`TTree::Process` is aware of PROOF, ROOT’s parallel processing facility. If PROOF is setup, it divides the processing amongst the slave CPUs.
Performance Benchmarks

The program `$ROOTSYS/test/bench.cxx` compares the I/O performance of STL vectors to the ROOT native `TClonesArrays` collection class. It creates trees with and without compression for the following cases:

- `vector<THit>`, `vector<THit*>`, `TClonesArray(TObjHit)` not split
- `TClonesArray(TObjHit)` split.

The graphs show the two columns on the right which represent the split and non-split `TClonesArray`, are significantly lower than the vectors. The most significant difference is when reading a file without compression.

The file size with compression, write times with and without compression and the read times with and without compression all favor the `TClonesArray`.

Impact of Compression on I/O

This benchmark illustrates the pros and cons of the compression option. We recommend using compression when the time spent in I/O is small compared to the total processing time. In this case, if the I/O operation is increased by a factor of 5 it is still a small percentage of the total time and it may very well save a factor of 10 on disk space. On the other hand if the time spend on I/O is large, compression may slow down the program's performance.

The standard test program `$ROOTSYS/test/Event` was used in various configurations with 400 events. The data file contains a `TTree`. The program was invoked with:

```
Event 400 comp split
```

- `comp = 0` means: no compression at all.
- `comp = 1` means: compress everything if `split = 0`.
- `comp = 1` means: compress only the tree branches with `split = 1`.
- `comp = 2` means: compress everything if `split=1`.
- `split = 0` : the full event is serialized into one single buffer.
- `split = 1` : the event is split into branches. One branch for each data member of the Event class. The list of tracks (a `TClonesArray`) has the data members of the Track class also split into individual buffers.

The graphs show the two columns on the right which represent the split and non-split `TClonesArray`, are significantly lower than the vectors. The most significant difference is when reading a file without compression.

The file size with compression, write times with and without compression and the read times with and without compression all favor the `TClonesArray`.

**Event Parameters**

<table>
<thead>
<tr>
<th>Event Parameters</th>
<th>File Size</th>
<th>Total Time to write (MB/sec)</th>
<th>Effective Time to write (MB/sec)</th>
<th>Total time to read All (MB/sec)</th>
<th>Total time to read Sample (MB/sec)</th>
</tr>
</thead>
<tbody>
<tr>
<td>Comp = 0 Split   = 1</td>
<td>19.75 MB</td>
<td>6.84 s. (2.8 MB/s)</td>
<td>3.56 s. (5.4 MB/s)</td>
<td>0.79 s. (24.2 MB/s)</td>
<td>0.79 s. (24.2 MB/s)</td>
</tr>
<tr>
<td>Comp = 1 Split   = 1</td>
<td>17.73 MB</td>
<td>6.44 s. (3.0 MB/s)</td>
<td>4.02 s. (4.8 MB/s)</td>
<td>0.90 s. (21.3 MB/s)</td>
<td>0.90 s. (21.3 MB/s)</td>
</tr>
<tr>
<td>Comp = 2 Split   = 1</td>
<td>13.78 MB</td>
<td>11.34 s. (1.7 MB/s)</td>
<td>9.51 s. (2.0 MB/s)</td>
<td>2.17 s. (8.8 MB/s)</td>
<td>2.17 s. (8.8 MB/s)</td>
</tr>
</tbody>
</table>

The **Total Time** is the real time in seconds to run the program.

**Effective time** is the real time minus the time spent in non I/O operations (essentially the random number generator).

The program `Event` generates in average 600 tracks per event. Each track has 17 data members.

The read benchmark runs in the interactive version of ROOT. The **Total time to read All** is the real time reported by the execution of the script `$ROOTSYS/test/eventa`. We did not correct this time for the overhead coming from the interpreter itself.

The **Total time to read Sample** is the execution time of the script `$ROOTSYS/test/eventb`. This script loops on all events. For each event, the branch containing the number of tracks is read. In case the number of tracks is less than 585, the full event is read in memory. This test is obviously not possible in non-split mode. In non-split mode, the full event must be read in memory.
The times reported in the table correspond to complete I/O operations necessary to deal with machine independent binary files. On Linux, this also includes byte-swapping operations. The ROOT file allows for direct access to any event in the file and also direct access to any part of an event when split=1.

Note also that the uncompressed file generated with split=0 is 48.7 Mbytes and only 47.17 Mbytes for the option split=1. The difference in size is due to the object identification mechanism overhead when the event is written to a single buffer. This overhead does not exist in split mode because the branch buffers are optimized for homogeneous data types.

You can run the test programs on your architecture. The program Event will report the write performance. You can measure the read performance by executing the scripts eventa and eventb. The performance depends not only of the processor type, but also of the disk devices (local, NFS, AFS, etc.).

Chains

A TChain object is a list of ROOT files containing the same tree. As an example, assume we have three files called file1.root, file2.root, file3.root. Each file contains one tree called "T". We can create a chain with the following statements:

```c
TChain chain("T"); // name of the tree is the argument
chain.Add("file1.root");
chain.Add("file2.root");
chain.Add("file3.root");
```

The name of the TChain will be the same as the name of the tree, in this case it will be "T". Note that two objects can have the same name as long as they are not histograms in the same directory, because there, the histogram names are used to build a hash table.

The class TChain is derived from the class TTree. For example, to generate a histogram corresponding to the attribute "x" in tree "T" by processing sequentially the three files of this chain, we can use the TChain::Draw method.

```c
chain.Draw("x");
```

The following statements illustrate how to set the address of the object to be read and how to loop on all events of all files of the chain.

```c
TChain chain("T"); // create the chain with tree "T"
chain.Add("file1.root"); // add the files
chain.Add("file2.root");
chain.Add("file3.root");
TH1F *hnseg = new TH1F("hnseg", 
"Number of segments for selected tracks",5000,0,5000);
// create an object before setting the branch address
Event *event = new Event();
// Specify the address where to read the event object
chain.SetBranchAddress("event", &event);
// Start main loop on all events
// In case you want to read only a few branches, use
// TChain::SetBranchStatus to activate a branch.
Int_t nevent = chain.GetEntries();
for (Int_t i=0;i<nevent;i++) {
  // read complete accepted event in memory
  chain.GetEvent(i);
  // Fill histogram with number of segments
  hnseg->Fill(event->GetNseg());
}
// Draw the histogram
hnseg->Draw();
```

TChain::AddFriend

A TChain has a list of friends similar to a tree (see TTree::AddFriend). You can add a friend to a chain with the TChain::AddFriend method, and you can retrieve the list of friends with TChain::GetListOfFriends.

This example has four chains each has 20 ROOT trees from 20 ROOT files.

```c
TChain ch("t"); // a chain with 20 trees from 20 files
TChain ch1("t1");
TChain ch2("t2");
TChain ch3("t3");
```

Now we can add the friends to the first chain.

```c
ch.AddFriend("t1")
ch.AddFriend("t2")
ch.AddFriend("t3")
```

The parameter is the name of friend chain (the name of a chain is always the name of the tree from which it was created).

The original chain has access to all variables in its friends. We can use the TChain::Draw method as if the values in the friends were in the original chain.
To specify the chain to use in the `Draw` method, use the syntax:

```
<chainname>.<branchname>.<varname>
```

If the variable name is enough to uniquely identify the variable, you can leave out the chain and/or branch name.

For example, this generates a 3-d scatter plot of variable "var" in the `TChain ch` versus variable `v1` in `TChain t1` versus variable `v2` in `TChain t2`.

```
ch.Draw("var:t1.v1:t2.v2");
```

When a `TChain::Draw` is executed, an automatic call to `TTree::AddFriend` connects the trees in the chain. When a chain is deleted, its friend elements are also deleted.

![Diagram showing connections between chains and files](image)

The number of entries in the friend must be equal or greater to the number of entries of the original chain. If the friend has fewer entries a warning is given and the resulting histogram will have missing entries.

For additional information see `TTree::AddFriends`. A full example of a tree and friends is in Example #3 (`$ROOTSYS/tutorials/tree3.c`) in the Tree section above.
13 Adding a Class

The Role of TObject

The light-weight TObject class provides the default behavior and protocol for the objects in the ROOT system. Specifically, it is the primary interface to classes providing object I/O, error handling, inspection, introspection, and drawing. The interface to these service is via abstract classes.

Introspection, Reflection and Run Time Type Identification

Introspection, which is also referred to as reflection, or run time type identification (RTTI), is the ability of a class to reflect upon itself or to "look inside itself." ROOT implements reflection with the TClass class. It provides all the information about a class, a full description of data members and methods, including the comment field and the method parameter types. A class with the ClassDef macro, has the ability to obtain a TClass with the IsA method.

```
TClass *cl = obj->IsA();
```

which returns a TClass. In addition an object can directly get the class name and the base classes with:

```
const char* name = obj->ClassName();
```

which returns a character string containing the class name. If the class is a descendent of TObject, you can check if an object inherits from a specific class, you can use the InheritsFrom method. This method returns kTrue if the object inherits from the specified class name or TClass.

```
Bool_t b = obj->InheritsFrom("TLine");
Bool_t b = obj->InheritsFrom(TLine::Class());
```

ROOT and CINT rely on reflection and the class dictionary to identify the type of a variable at run time.

With TObject inheritance come some methods that use introspection to help you see the data in the object or class. For instance:

```
obj->Dump();           // lists all data members and
obj->Inspect();       // their current value
obj->DrawClass();     // the data members at all levels
obj->DrawClass();     // draws the class inheritance tree

For an example of obj->Inspect see "Inspecting ROOT Objects" in the CINT chapter.

Collections

To store an object in a ROOT collection, it must be a descendent of TObject. This is convenient if you want to store objects of different classes in the same collection and execute the method of the same name on all members of the collection. For example the list of graphics primitives are in a ROOT collection called TList. When the canvas is drawn the Paint method is executed on the entire collection. Each member may be a different class, and if the Paint method is not implemented, TObject::Paint will be executed.

Input/Output

The TObject::Write method is the interface to the ROOT I/O system. It streams the object into a buffer using the Streamer method. It support cycle numbers and automatic schema evolution (see the chapter on I/O).

Paint/Draw

These two graphics methods are defaults, their implementation in TObject does not use the graphics subsystem. The TObject::Draw method is simply a call to AppendPad. The Paint method is empty. The default is provided so that one can call Paint in a collection.

GetDrawOption

This method returns the draw option that was used when the object was drawn on the canvas. This is especially relevant with histograms and graphs.

Clone/DrawClone

Two useful methods are Clone and DrawClone. The Clone method takes a snapshot of the object with the Streamer and creates a new object. The DrawClone method does the same thing and in addition draws the clone.

Browse

This method is called if the object is browse-able and is to be displayed in the object browser. For example the TBranch implementation of Browse, calls the Browse method for each branch. The TBranch::Browse method displays the name of each leaf. For the object's Browse method to be called, the IsFolder() method must be overridden to return true. This does not mean it has to be a folder, it just means that it is browse-able.
SavePrimitive
This method is called by a canvas on its list of primitives, when the canvas is saved as a script. The purpose of SavePrimitive is to save a primitive as a C++ statement(s). Most ROOT classes implement the SavePrimitive method. It is recommended that the SavePrimitive is implemented in user defined classes if it is to be drawn on a canvas. Such that the command TCanvas::SaveAs(Canvas.C) will preserve the user-class object in the resulting script.

GetObjectInfo
This method is called when displaying the event status in a canvas. To show the event status window, select the Options menu and the Event Status item. This method returns a string of information about the object at position (x, y). Every time the cursor moves, the object under the cursor executes the GetObjectInfo method. The string is then shown in the status bar.

There is a default implementation in TObject, but it is typically overridden for classes that can report peculiarities for different cursor positions (for example the bin contents in a TH1).

IsFolder
By default an object inheriting from TObject is not brows-able, because TObject::IsFolder() returns kFALSE. To make a class browse-able, the IsFolder method needs to be overridden to return kTRUE.

In general, this method returns kTRUE if the object contains browse-able objects (like containers or lists of other objects).

Bit Masks and Unique ID
A TObject descendant inherits two data members: fBits and fUniqueID. fBits: This 32-bit data member is to be used with a bit mask to get information about the object. Bit 0 – 7 are reserved by TObject. The kMustClean, kCanDelete are used in TObject, these can be set by any object and should not be reused. 

These are the bits used in TObject:

```c
enum OBJBits {
    kCanDelete = BIT(0), // if object in a list can be deleted
    kMustCleanUp = BIT(3), // if object destructor must call RecursiveRemove()
    kCannotPick = BIT(6), // if object in a pad cannot be picked
    kInvalidObject = BIT(13) // object should not be used
};
```

The remaining 24 bits can be used by other classes. Make sure there is no overlap in any given hierarchy. For example TClass uses bit 12 and 13 kClassSaved and kIgnoreTObjectStreamer respectively. 

The above bit 13 is set when an object could not be read from a ROOT file. It will check this bit and skip to the next object on the file.

The TObject constructor initializes the fBits to zero depending if the object is created on the stack or allocated on the heap. When the object is created on the stack, the kCanDelete bit is set to false to protect from deleting objects on the stack. Of the status word the high 8 bits are reserved for system usage and the low 24 bits are user saitable.

fUniqueID: This data member can be used to give an object a unique identification number. It is initialized to zero by the TObject constructor. This data member is not used by ROOT.

These two data members are streamed out when writing an object to disk. If you do not use them you can save some space and time by specifying:

```cpp
MyClass::Class()->IgnoreTObjectStreamer()
```

This sets a bit in the TClass object.

If the file is compressed, the savings are minimal since most values are zero, however, it saves some space when the file is not compressed.

A call to IgnoreObjectStreamer also prevents the creation of two additional branches when splitting the object. If left alone, two branches called fBits and fUniqueID will appear.

Motivation
If you want to integrate and use your classes with ROOT, to enjoy features like, extensive RTTI (Run Time Type Information) and ROOT object I/O and inspection, you have to add the following line to your class header files:

```cpp
ClassDef (ClassName, ClassVersionID)  //The class title
```

For example in TLine.h we have:

```cpp
ClassDef (TLine,1)  //A line segment
```

The ClassVersionID is used by the ROOT I/O system. It is written on the output stream and during reading you can check this version ID and take appropriate action depending on the value of the ID (see the section on Streamers in the Chapter Input/Output). Every time you change the data members of a class, you should increase its ClassVersionID by one. The ClassVersionID should be >=1. Set ClassVersionID=0 in case you don't need object I/O.

Similarly, in your implementation file you must add the statement:

```cpp
ClassImp(ClassName)
```

For example in TLine.cxx:

```cpp
ClassImp(TLine)
```

Note that you MUST provide a default constructor for your classes, i.e. a constructor with zero parameters or with one or more parameters all with default values in case you want to use object I/O. If not you will get a compile time error.

The ClassDef and ClassImp macros are necessary to link your classes to the dictionary generated by CINT.
The `ClassDef` and `ClassImp` macros are defined in the file `Rtypes.h`. This file is referenced by all ROOT include files, so you will automatically get them if you use a ROOT include file.

**Template Support**

ROOT provides `ClassDef` and `ClassImp` macros for classes with two and three template arguments. The macros are: `ClassDefT`, `ClassDef2T2`, `ClassDef3T3` and `ClassImpT`, `ClassImp2T`, `ClassImp3T`.

- `ClassDefT` is independent of the number of template arguments.
- For templates the `ClassImp` must be in the header file. When you use templates in principle all the code is defined in the header. Then when a special "instantiation" is needed the compiler takes the code in the header and generates the real code (i.e. replaces the `T` by `int`, where `T` was the template argument). So for templated classes it is normal to put the `ClassImp` in the header.

Here is an example of a header `LinkDef` file:

```cpp
// in header file MyClass.h
template <typename T> class MyClass1 {
  private:
    T  fA;
    ...
  public:
    ...
  ClassDefT(MyClass1,1)
};
ClassDef2T(MyClass1,T) ClassImpT(MyClass1,T)

template <typename T1, typename T2> class MyClass2 {
  private:
    T1  fA;
    T2  fB;
    ...
  public:
    ...
  ClassDefT(MyClass2,1)
};
ClassDef2T(MyClass2,T1,T2) ClassImp2T(MyClass2,T1,T2)

template <typename T1, typename T2, typename T3> class MyClass3 {
  private:
    T1  fA;
    T2  fB;
    T3  fC;
    ...
  public:
    ...
  ClassDefT(MyClass3,1)
};
ClassDef3T2T(MyClass3,T1,T2,T3) ClassImp3T(MyClass3,T1,T2,T3)
```

**The Default Constructor**

ROOT object I/O requires every class to have a default constructor. This default constructor is called whenever an object is being read from a ROOT database. Be sure that you don’t allocate any space for embedded pointer objects in the default constructor. This space will be lost (memory leak) while reading in the object. For example:

```cpp
class T49Event : public TObject {
  private:
    Int_t        fId;
    TCollection *fTracks;
    ...
  public:
  // Error space for TList pointer will be lost
  T49Event() { fId = 0; fTrack = new TList; }
  // Correct default initialization of pointer
  T49Event() { fId = 0; fTrack = 0; }
  ...

  if (!fTrack) fTrack = new TList;
};
```

The memory will be lost because during reading of the object the pointer will be set to the object it was pointing to at the time the object was written.

Create the `fTrack` list when you need it, e.g. when you start filling the list or in a non-default constructor.
The usage of the ClassDef macro
The default constructors of the TEvent and TTrack classes
Comments to describe the data members and the comment after the ClassDef macro to describe the class

These classes are intended for you to create an event object with a certain id, and then add tracks to it. The track objects have a pointer to their event. This shows that the I/O system correctly handles circular references.
Next, the implementation of these two classes.

**Event.cxx:**

```c++
#include <iostream.h>
#include "TOrdCollection.h"
#include "TEvent.h"
#include "TTrack.h"

ClassImp(TEvent)
...
...

and **Track.cxx:**

```c++
#include <iostream.h>
#include "TMath.h"
#include "Track.h"
#include "Event.h"

ClassImp(TTrack)
...
...
```

Now using rootcint we can generate the dictionary file.

Make sure you use a unique filename, because rootcint appends it to the name of static function (G__cpp_reset_tabableeventdict() and G__set_cpp_environmenteventdict()).

rootcint eventdict.cxx -c TEvent.h TTrack.h

Looking in the file eventdict.C we can see, besides the many member function calling stubs (used internally by the interpreter), the Streamer() and ShowMembers() methods for the two classes. Streamer() is used to stream an object to/from a TBuffer and ShowMembers() is used by the Dump() and Inspect() methods of TObject.

Here is the TEvent::Streamer method:

```c++
void TEvent::Streamer(TBuffer &R__b)
{
  // Stream an object of class TEvent.
  if (R__b.IsReading()) {
    Version_t R__v = R__b.ReadVersion();
    TObject::Streamer(R__b);
    R__b >> fId;
    R__b >> fTotalMom;
    R__b >> fTracks;
  } else {
    R__b.WriteVersion(TEvent::IsA());
    TObject::Streamer(R__b);
    R__b << fId;
    R__b << fTotalMom;
    R__b << fTracks;
  }
}
```

The TBuffer class overloads the operator<<() and operator>>() for all basic types and for pointers to objects. These operators write and read from the buffer and take care of any needed byte swapping to make the buffer machine independent. During writing the TBuffer keeps track of the objects that have been written and multiple references to the same object are replaced by an index. In addition, the object's class information is stored.

TEvent and TTracks need manual intervention. Cut and paste the generated Streamer() from the eventdict.C into the class' source file and modify as needed (e.g. add counter for array of basic types) and disable the generation of the Streamer() when using the LinkDef.h file for next execution of rootcint.

In case you don't want to read or write this class (no I/O) you can tell rootcint to generate a dummy Streamer() by changing this line in the source file:

```
ClassDef (TEvent,0)
```

If you want to prevent the generation of Streamer(), see the chapter "Adding a Class with a Shared Library" below.
Adding a Class with a Shared Library

Step 1:
Define your own class in SClass.h and implement it in SClass.cxx. You must provide a default constructor for your class.

```c
#include <iostream.h>
#include "TObject.h"
class SClass : public TObject {
private:
  Float_t   fX;     // x position in centimeters
  Float_t   fY;     // y position in centimeters
  Int_t     fTempValue;   // temporary state value
public:
  SClass()             { fX = fY = -1; }
  void Print() const;
  void SetX(float x) { fX = x; }
  void SetY(float y) { fY = y; }
ClassDef (SClass, 1)
};
```

Step 2:
Add a call to the ClassDef macro at the end of the class definition (i.e. in the SClass.h file). Add a call to the ClassImp macro in the implementation file (SClass.cxx). ClassImp(SClass)

```c
#include "SClass.h"
ClassImp (SClass);
void SClass::Print() const {
  cout << "fX = " << fX << " fY = " << fY << endl;
}
```

You can add a class without using the ClassDef and ClassImp macros, however you will be limited. Specifically, the object I/O features of ROOT will not be available to you for these classes (see the chapter "CINT the C++ Interpreter").

The ShowMembers() andStreamer() method, as well as the operator overloads, are implemented only if you use ClassDef and ClassImp.

See http://root.cern.ch/root/html/Rtypes.h for the definition of ClassDef and ClassImp.

To exclude a data member from the Streamer, add a ! as the first character in the comments of the field:

```
Int_t     fTempValue;   // temporary state value
```

The LinkDef.h File

Step 3:
The LinkDef.h file tells rootcint for which classes to generate the method interface stubs.

```c
#ifdef __CINT__
#pragma link off all globals;
#pragma link off all classes;
#pragma link off all functions;
#pragma link C++ class SClass;
#endif
```

Three options can trail the class name:

- - : tells rootcint not to generate the Streamer() method for this class. This is necessary for those classes that need a customized Streamer() method.

```c
#pragma link C++ class SClass-;
// no streamer
```

- !: tells rootcint not to generate the operator>>(TBuffer &b, MyClass *&obj) method for this class. This is necessary to be able to write pointers to objects of classes not inheriting from TObject.

```c
#pragma link C++ class SClass!;
// no >> operator
```

- +: in ROOT version 1 and 2 tells rootcint to generate a Streamer() with extra byte count information. This adds an integer to each object in the output buffer, but it allows for powerful error correction in case a Streamer() method is out of sync with data in the file. The + option is mutually exclusive with both the - and ! options.

```c
#pragma link C++ class SClass+;
// add byte count
```

IMPORTANT NOTE: In ROOT Version 3, a + after the class name tells rootcint to use the new I/O system. The byte count check is always added.

```c
#pragma link C++ class SClass+; // add byte count
```

For information on Streamers see the section on Streamers in the Input/Output chapter.

To get help on rootcint type: rootcint -? on the UNIX command line.

The Order Matters

When using templated classes, the order of the pragma statements matters. For example, here is a templated class Tmpl and a normal class Norm which holds a specialized instance of a Tmpl:

```c
#include <iostream.h>
#include "TObject.h"
```
class Norm {
private:
    Tmpl<int>* fIntTmpl;
public:
    ~;
};

Then in Linkdef.h the pragma statements must be ordered by listing all
specializations before any classes which need them:

// Correct Linkdef.h ordering
#pragma link C++ class Tmpl<int>
#pragma link C++ class Norm;
// Bad Linkdef.h ordering
#pragma link C++ class Norm
#pragma link C++ class Tmpl<int>

In this later case, rootcint generates Norm::Streamer() which makes
reference to Tmpl<int>::Streamer(). Then rootcint gets to process
Tmpl<int> and generates a specialized Tmpl<int>::Streamer() function.

The problem is, when the compiler finds the first
Tmpl<int>::Streamer(), it will instantiate it. But, later in the file
it finds the specialized version that rootcint generated. This causes
the error.

However, if the Linkdef.h order is reversed then rootcint can generate
the specialized Tmpl<int>::Streamer() before it is needed (and thus
never instantiated by the compiler).

Step 4: Compile the class using the Makefile

In the Makefile call rootcint to make the dictionary for the class. Call it
SClassDict.cxx. The rootcint utility generates the Streamer(), TBuffer
&operator>>() and ShowMembers() methods for ROOT classes.

For more information on rootcint follow this link:
http://root.cern.ch/node/RodCInstMan.html

Also, see the $ROOTSYS/test directory Makefile, Event.cxx, and
Event.h for an example.

Adding a Class with ACLiC

Step 1. Define your class

#include "TObject.h"
// define the ABC class and make it inherit
// from TObject so that we can write ABC to a ROOT file
class ABC : public TObject {
public:
    Float_t a,b,c,p;
    ABC():a(0),b(0),c(0),p(0){};
    // Define the class for the cint dictionary
    ClassDef (ABC,1)
};

    // Call the ClassImp macro to give the ABC class RTTI
    // and full I/O capabilities.
    #if !defined(__CINT__)
    ClassImp(ABC);
    #endif

Step 2: Load the ABC class in the script.

// Check if ABC is already loaded
if (!TClassTable::GetDict("ABC")) {
    gROOT->Macro("ABCClass.C++");
}
// Use the class
ABC *v = new ABC;
v->p = (sqrt((v->a * v->a)+(v->b * v->b)+(v->c * v->c)));
14 Collection Classes

Collections are a key feature of the ROOT system. Many, if not most, of the applications you write will use collections. If you have used parameterized C++ collections or polymorphic collections before, some of this material will be review. However, much of this chapter covers aspects of collections specific to the ROOT system. When you have read this chapter, you will know:

- How to create instances of collections
- The difference between lists, arrays, hash tables, maps, etc.
- How to add and remove elements of a collection
- How to search a collection for a specific element
- How to access and modify collection elements
- How to iterate over a collection to access collection elements
- How collection elements are tested for equality (IsEqual())
- How collection elements are compared (Compare()) in case of sorted collections
- How collection elements are hashed (Hash()) in hash tables

Understanding Collections

A collection is a group of related objects. You will find it easier to manage a large number of items as a collection. For example, a diagram editor might manage a collection of points and lines. A set of widgets for a graphical user interface can be placed in a collection. A geometrical model can be described by collections of shapes, materials and rotation matrices. Collections can themselves be placed in collections. Collections act as flexible alternatives to traditional data structures of computers science such as arrays, lists and trees.

General Characteristics

The ROOT collections are polymorphic containers that hold pointers to TObject, so:

- They can only hold objects that inherit from TObject
- They return pointers to TObject, that have to be cast back to the correct subclass

Collections are dynamic, they can grow in size as required.

Determining the Class of Contained Objects

Most containers may hold heterogeneous collections of objects and then it is left to the user to correctly cast the TObject pointer to the right class. Casting to the wrong class will give wrong results and may well crash the program! So the user has to be very careful. Often a container only contains one class of objects, but if it really contains a mixture, it is possible to ask each object about its class using the InheritsFrom() method.

For example if myObject is a TObject pointer:

```c
if (myObject->InheritsFrom("TParticle") {  
    printf("myObject is a TParticle\n");  
}
```

As the name suggests, this test works even if the object is a subclass of TParticle. The member function IsA() can be used instead of InheritsFrom() to make the test exact. The InheritsFrom() and IsA() methods use the extensive Run Time Type Information (RTTI) available via the ROOT meta classes.

Types of Collections

The ROOT system implements the following basic types of collections: unordered collections, ordered collections and sorted collections. This picture shows the inheritance hierarchy for the primary collection classes. All primary collection classes derive from the abstract base class TCollection.
Ordered Collections (Sequences)

Sequences are collections that are externally ordered because they maintain internal elements according to the order in which they were added. The following sequences are available:

- TList
- THashList
- TOrdCollection
- TObjectArray
- TClonesArray

The TOrdCollection, TObjectArray as well as the TClonesArray can be sorted using their Sort() member function (if the stored items are sort able). Ordered collections all derive from the abstract base class TSeqCollection.

Sorted Collection

Sorted collections are ordered by an internal (automatic) sorting mechanism. The following sorted collections are available:

- TSortedList
- TBtree

The stored items must be sort able.

Unordered Collections

Unordered collections don't maintain the order in which the elements were added, i.e. when you iterate over an unordered collection, you are not likely to retrieve elements in the same order they were added to the collection. The following unordered collections are available:

- THashTable
- TMap

Iterators: Processing a Collection

The concept of processing all the members of a collection is generic, i.e. independent of any specific representation of a collection. To process each object in a collection one needs some type of cursor that is initialized and then steps over each member of the collection in turn. Collection objects could provide this service but there is a snap: as there is only one collection object per collection there would only be one cursor. Instead, to permit the use of as many cursors as required, they are made separate classes called iterators. For each collection class there is an associated iterator class that knows how to sequentially retrieve each member in turn. The relationship between a collection and its iterator is very close and may require that the iterator has full access to the collection (i.e. it is a friend class). In general iterators will be used via the TIter wrapper class.

For example:

- TList TListIter
- TMap TMapIter

Foundation Classes

All collections are based on the fundamental classes: TCollection and TIterator. They are so generic that it is not possible to create objects from them; they are only used as base classes for other classes (i.e. they are abstract base classes).

TCollection

The TCollection class provides the basic protocol (i.e. the minimum set of member functions) that all collection classes have to implement. These include:

- Add() Adds another object to the collection.
- GetSize() Returns the number of objects in the collection.
- Clear() Clears out the collection, but does not delete the removed objects.
- Delete() Clears out the collection and deletes the removed objects. This should only be used if the collection owns its objects (which is not normally the case).

- FindObject() Find an object given either its name or address.
- MakeIterator() Returns an iterator associated with the collection.
- Remove() Remoes an object from the collection.

Coming back to the issue of object ownership. The code example below shows a class containing three lists, where the fTracks list is the owning collection and the other two lists are used to store a sub-set of the track objects. In the destructor of the class the Delete() method is called for the owning collection to delete correctly all its track objects.

To delete the objects in the container, do 'fTracks->Delete()'. To delete the container itself do 'delete fTracks'.

```cpp
class TEvent : public TObject {
private:
  TList *fTracks; //list of all tracks
  TList *fVertex1; //subset of tracks part of vertex1
  TList *fVertex2; //subset of tracks part of vertex2

  ~TEvent() {
    fTracks->Delete(); delete fTracks;
    delete fVertex1; delete fVertex2;
  }
};
```

TIterator

The TIterator class defines the minimum set of member functions that all iterators must support. These include:

- Next() return the next member of the collection or 0 if no more members.
- Reset() reset the iterator so that Next() returns the first object.
A Collectable Class

By default, all objects of TObject derived classes can be stored in ROOT containers. However, the TObject class provides some member functions that allow you to tune the behavior of objects in containers. For example, by default two objects are considered equal if their pointers point to the same address. This might be too strict for some classes where equality is already achieved if some or all of the data members are equal. By overriding the following TObject member functions, you can change the behavior of objects in collections:

- IsEqual() is used by the FindObject() collection method. By default, IsEqual() compares the two object pointers.
- Compare() returns -1, 0 or 1 depending if the object is smaller, equal or larger than the other object. By default, a TObject has not a valid Compare() method.
- IsSortable() returns true if the class is sort able (i.e. if it has a valid Compare() method). By default, a TObject is not sort able.
- Hash() returns a hash value. It needs to be implemented if an object has to be stored in a collection using a hashing technique, like THashTable, THashList and TMap. By default, Hash() returns the address of the object. It is essential to choose a good hash function.

The example below shows how to use and override these member functions.

```cpp
// TObjNum is a simple container for an integer.
class TObjNum : public TObject {
private:
  int  num;
public:
  TObjNum(int i = 0) : num(i) { }
  ~TObjNum() { }
  void     SetNum(int i) { num = i; }
  int      GetNum() const { return num; }
  void     Print(Option_t *) { printf("num = %d\n", num); }
  Bool_t   IsEqual(TObject *obj)
  { return num == ((TObjNum*)obj)->num; }
  Bool_t   IsSortable() const { return kTRUE; }
  Int_t    Compare(TObject *obj)
  { if (num < ((TObjNum*)obj)->num) return -1;
    else if (num > ((TObjNum*)obj)->num) return 1;
    else return 0; }
  ULong_t  Hash() { return num; }
};
```

The TIter Generic Iterator

As stated above, the TIterator class is abstract; it is not possible to create TIterator objects. However, it should be possible to write generic code to process all members of a collection so there is a need for a generic iterator object. A TIter object acts as generic iterator. It provides the same Next() and Reset() methods as TIterator although it has no idea how to support them! It works as follows:

- To create a TIter object its constructor must be passed an object that inherits from TCollection. The TIter constructor calls the MakeIterator() method of this collection to get the appropriate iterator object that inherits from TIterator.
- The Next() and Reset() methods of TIter simply call the Next() and Reset() methods of the iterator object.

So TIter simply acts as a wrapper for an object of a concrete class inheriting from TIterator.

To see this working in practice, consider the TObjArray collection. Its associated iterator is TObjectArrayIter. Suppose myarray is a pointer to a TObjectArray, i.e.

```cpp
TObjArray *myarray;
Which contains MyClass objects. To create a TIter object called myiter:
TIter myiter(myarray);
```

As shown in the diagram, this results in several methods being called:

1. TIter myiter(myarray)
2. MakeIterator
3. MakeIterator
4. TObjArrayiter

As shown in the diagram, this results in several methods being called:

(1) The TIter constructor is passed a TObjectArray
(2) TIter asks embedded TCollection to make an iterator
(3) TCollection asks TObjectArray to make an iterator
(4) TObjectArray returns a TObjectArrayIter.
Now define a pointer for MyClass objects and set it to each member of the TObjArray:

```c
MyClass *myobject;
while (myobject = (MyClass *) myiter.Next()) {
    // process myobject
}
```

The heart of this is the `myiter.Next()` expression which does the following:

1. The `Next()` method of the `TIterator` object `myiter` is called
2. The `TIter` forwards the call to the `TIterator` embedded in the `TObjArrayIter`
3. `TIterator` forwards the call to the `TObjArrayIter`
4. `TObjArrayIter` finds the next MyClass object and returns it
5. `TIter` passes the MyClass object back to the caller

Sometimes the `TIter` object is called `next`, and then instead of writing:

```c
next.Next()
```

which is legal, but looks rather odd, iteration is written as:

```c
next()
```

This works because the function `operator()` is defined for the `TIter` class to be equivalent to the `Next()` method.

---

### The TList Collection

A TList is a doubly linked list. Before being inserted into the list the object pointer is wrapped in a TObjLink object that contains, besides the object pointer also a previous and next pointer.

Objects are typically added using:

- `Add()`
- `AddFirst()`, `AddLast()`
- `AddBefore()`, `AddAfter()`

**Main features of TList**: very low cost of adding/removing elements anywhere in the list.

**Overhead per element**: 1 TObjLink, i.e. two 4 (or 8) byte pointers + pointer to vtable = 12 (or 24) bytes.

```c
class TList : public TSeqCollection {
private:
    TObjLink *fLast;
    TObjLink *fFirst;
    ... ...
};
```

```c
class TObjLink {
friend class TList;
private:
    TObjLink *fPrev;
    TObjLink *fNext;
    TObject *fObject;
    ... ...
};
```

The diagram below shows the internal data structure of a TList:
Iterating over a TList

There are basically four ways to iterate over a TList:

1. Using the ForEach script:
   ```
   GetListOfPrimitives()->ForEach(TObject,Draw());
   ```

2. Using the TList iterator TListIter (via the wrapper class TIter):
   ```
   TIter next(GetListOfTracks());
   while ((TTrack *obj = (TTrack *)next()))
       obj->Draw();
   ```

3. Using the TObjectLink list entries (that wrap the TObject*):
   ```
   TObjectLink *lnk = GetListOfPrimitives()->FirstLink();
   while (lnk) {
       lnk->GetObject()->Draw();
       lnk = lnk->Next();
   }
   ```

4. Using the TList’s After() and Before() member functions:
   ```
   TFree *idcur = this;
   while (idcur) {
       ...
       obj = (TFree*)GetListOfFree()->After(idcur);
       ...
   }
   ```

Method 1 uses internally method 2.
Method 2 works for all collection classes. TIter overloads operator().
Methods 3 and 4 are specific for TList.
Methods 2, 3 and 4 can also easily iterate backwards using either a backward TIter (using argument kIterBackward) or by using LastLink() and lnk->Prev() or by using the Before() method.

The TObjectArray Collection

A TObjectArray is a collection which supports traditional array semantics via the overloading of operator[]. Objects can be directly accessed via an index. The array expands automatically when objects are added.

At creation time one specifies the default array size (default = 16) and lower bound (default = 0). Resizing involves a re-allocation and a copy of the old array to the new. This can be costly if done too often. If possible, set initial size close to expected final size. Index validity is always checked (if you are 100% sure and maximum performance is needed you can use UnCheckedAt() instead of At() or operator[]).

If the stored objects are sort able the array can be sorted using Sort[]. Once sorted, efficient searching is possible via the BinarySearch() method.

Iterating can be done using a TIter iterator or via a simple for loop:
```
for (int i = 0; i <= fArr.GetLast(); i++)
    if ((track = (TTrack*)fArr[i])) // or fArr.At(i)
        track->Draw();
```
A `TClonesArray` is an array of identical (clone) objects. The memory for the objects stored in the array is allocated only once in the lifetime of the clones array. All objects must be of the same class and the object must have a fixed size (i.e. they may not allocate other objects). For the rest this class has the same properties as a `TObjArray`.

The class is specially designed for repetitive data analysis tasks, where in a loop many times the same objects are created and deleted.

The diagram below shows the internal data structure of a `TClonesArray`:

The Idea Behind TClonesArray

To reduce the very large number of new and delete calls in large loops like this \(O(100000) \times O(10000)\) times new/delete:

```cpp
tobjarray a(10000); while (TEvent *ev = (TEvent *)next()) { // O(100000) for (int i = 0; i < ev->Ntracks; i++) { // O(10000) a[i] = new TTrack(x,y,z,...); ... } a.Delete(); }
```

Considering that a pair of new/delete calls on average cost about 70 µs, \(O(10^9)\) new/deletes will save about 19 hours.

For the other collections see the class reference guide on the web and the test program `$ROOTSYS/test/tcollex.cxx`.

Template Containers and STL

Some people dislike polymorphic containers because they are not truly “type safe”. In the end, the compiler leaves it to the user to ensure that the types are correct. This only leaves the other alternative: creating a new class each time a new (container organization) / (contained object) combination is needed. To say the least this could be very tedious. Most people faced with this choice would, for each type of container:

1. Define the class leaving a dummy name for the contained object type.
2. When a particular container was needed, copy the code and then do a global search and replace for the contained class.

C++ has a built in template scheme that effectively does just this. For example:

```cpp
template<class T> class ArrayContainer {
private:
    T *member[10];
    ...;
};
```

This is an array container with a 10-element array of pointers to `T`, it could hold up to 10 `T` objects. This array is flawed because it is static and hard-coded, it should be dynamic. However, the important point is that the template statement indicates that `T` is a template, or parameterized class. If we need an `ArrayContainer` for `Track` objects, it can be created by:

```cpp
ArrayContainer<Track> MyTrackArrayContainer;
```

C++ takes the parameter list, and substitutes `Track` for `T` throughout the definition of the class `ArrayContainer`, then compiles the code so generated, effectively doing the same we could do by hand, but with a lot less effort. This produces code that is type safe, but does have different drawbacks:

- Templates make code harder to read.
At the time of writing this documentation, some compilers can be very slow when dealing with templates.

It does not solve the problem when a container has to hold a heterogeneous set of objects.

The system can end up generating a great deal of code; each container/object combination has its own code, a phenomenon that is sometimes referred to as **code bloat**.

The Standard Template Library (STL) is part on ANSI C++, and includes a set of template containers.
The physics vector classes describe vectors in three and four dimensions and their rotation algorithms. The classes were ported to root from CLHEP see: http://wwwinfo.cern.ch/asd/hc++/clhep/manual/UserGuide/Vector/vector.html

**The Physics Vector Classes**

There are four classes in this package. They are:

- **TVector3**: A general three vector class. A TVector3 may be expressed in Cartesian, polar, or cylindrical coordinates. Methods include dot and cross products, unit vectors and magnitudes, angles between vectors, and rotations and boosts. There are also functions of particular use to HEP, like pseudo-rapidity, projections, and transverse part of a TVector3, and kinetic methods on 4-vectors such as Invariant Mass of pairs or containers of particles.

- **TLorenzVector**: a general four-vector class, which can be used either for the description of position and time (x, y, z, t) or momentum and energy (px, py, pz, E).

- **TRotation**: a class describing a rotation of a TVector3 object.

- **TLorenzRotation**: a class to describe the Lorentz transformations including Lorentz boosts and rotations.

There is also a TVector2, it is a basic implementation of a vector in two dimensions and not part of the CLHEP translation.

**TVector3**

TVector3 is a general three vector class, which can be used for description of different vectors in 3D. Components of three vector:

- x, y, z - basic components
- θ = azimuth angle
- φ = polar angle
- magnitude = mag = sqrt(x^2 + y^2 + z^2)
- transverse component = perp = sqrt(x^2 + y^2)

Using the TVector3 class you should remember that it contains only common features of three vectors and lacks methods specific for some particular vector values. For example, it has no translate function because translation has no meaning for vectors.

**Declaration / Access to the components**

TVector3 has been implemented as a vector of three Double_t variables, representing the Cartesian coordinates. By default the values are initialized to zero, however you can change them in the constructor:

```
TVector3 v1;       // v1 = (0,0,0)
TVector3 v2(1);    // v2 = (1,0,0)
TVector3 v3(1,2,3); // v3 = (1,2,3)
TVector3 v4(v2);   // v4 = v2
```

It is also possible (but not recommended) to initialize a TVector3 with a Double_t or Float_t C array.

You can get the components by name or by index:

```
xx = v1.X();       or xx = v1(0);
yy = v1.Y();       or yy = v1(1);
zz = v1.Z();       or zz = v1(2);
```
The methods SetX(), SetY(), SetZ() and SetXYZ() allows you to set the components:

\begin{verbatim}
v1.SetX(1.); v1.SetY(2.); v1.SetZ(3.);
v1.SetXYZ(1.,2.,3.);
\end{verbatim}

Other Coordinates
To get information on the TVector3 in spherical (rho, phi, theta) or cylindrical (z, r, theta) coordinates, the following methods can be used.

\begin{verbatim}
Double_t m  = v.Mag();       // get magnitude (=rho=Sqrt(x*x+y*y+z*z))
Double_t m2 = v.Mag2();      // get magnitude squared
Double_t t  = v.Theta();     // get polar angle
Double_t ct = v.CosTheta();  // get cos of theta
Double_t p  = v.Phi();       // get azimuth angle
Double_t pp = v.Perp();      // get transverse component
Double_t pp2= v.Perp2();     // get transverse squared
\end{verbatim}

It is also possible to get the transverse component with respect to another vector:

\begin{verbatim}
Double_t ppv1  = v.Perp(v1);    // get transverse component to v1
Double_t pp2v1 = v.Perp2(v1);   // get transverse squared to v1
\end{verbatim}

The pseudo-rapidity (eta = -ln(tan(phi/2))) can be get by Eta() or PseudoRapidity():

\begin{verbatim}
Double_t eta = v.PseudoRapidity();
\end{verbatim}

These setters change one of the non-Cartesian coordinates:

\begin{verbatim}
v.SetTheta(.5); // keeping rho and phi
v.SetPhi(.8);  // keeping rho and theta
v.SetMag(10.); // keeping theta and phi
v.SetPerp(3.); // keeping z and phi
\end{verbatim}

Arithmetic / Comparison
The TVector3 class has operators to add, subtract, scale and compare vectors:

\begin{verbatim}
v1 = - v1;
v1 = v2+v3;
v1 *= v3;
v1 = v1 - v3;
v1 = 5*v2;
if(v1 == v2) {...}
if(v1 != v2) {...}
\end{verbatim}

Related Vectors
v2 = v1.Unit();       // get unit vector parallel to v1
v2 = v1.Oriental();   // get vector orthogonal to v1

Scalar and Vector Products
\begin{verbatim}
s  = v1.Dot(v2);      // scalar product
s  = v1 * v2;        // scalar product
v  = v1.Cross(v2);    // vector product
\end{verbatim}

Angle between Two Vectors

\begin{verbatim}
Double_t a = v1.Angle(v2);
\end{verbatim}

Rotation around Axes
v1.RotateX(.5);        // rotation around x axis
v1.RotateY(TMATH::Pi());  // rotation around y axis
v1.RotateZ(angle);     // rotation around z axis

Rotation around a Vector
v1.Rotate(TMATH::Pi()/4, v2);  // rotation around v2

Rotation by TRotation
TVector3 objects can be rotated by TRotation objects using the Transform() method, the operator *=, or the operator * of the TRotation class. See the later section on TRotation.

\begin{verbatim}
TRotation m;
... v1.transform(m);
v1 *= m;                          // v1 = m*v1
\end{verbatim}

Transformation from Rotated Frame
This code transforms v1 from the rotated frame (z' parallel to direction, x' in the theta plane and y' in the xy plane as well as perpendicular to the theta plane) to the (x, y, z) frame.

\begin{verbatim}
TVector3 direction = v.Unit();
v1.RotateUz(direction);            // direction must be TVector3 of unit length
\end{verbatim}
The TRotation class describes a rotation of TVector3 object. It is a 3 * 3 matrix of Double_t:

\[
\begin{pmatrix}
xx & xy & xz \\
yx & yy & yz \\
ZX & zy & zz
\end{pmatrix}
\]

It describes a so-called active rotation, i.e. a rotation of objects inside a static system of coordinates. In case you want to rotate the frame and want to know the coordinates of objects in the rotated system, you should apply the inverse rotation to the objects. If you want to transform coordinates from the rotated frame to the original frame you have to apply the direct transformation.

A rotation around a specified axis means counterclockwise rotation around the positive direction of the axis.

Declaration, Access, Comparisons

TRotation r; // r initialized as identity
TRotation m(r); // m = r

There is no direct way to set the matrix elements - to ensure that a TRotation always describes a real rotation. But you can get the values by with the methods XX()..ZZ() or the (,) operator:

```cpp
double xx = r.XX(); // the same as xx=r(0,0)
xx = r.XY();
if (r==m) {...} // test for equality
if (r!=m) {...} // test for inequality
if (r.IsIdentity()) {...} // test for identity
```

Rotation Around Axes

The following matrices describe counter-clockwise rotations around the coordinate axes and are implemented in RotateX(), RotateY() and RotateZ():

\[
\begin{align*}
Rx(a) &= \begin{pmatrix} 1 & 0 & 0 \\ 0 & \cos(a) & -\sin(a) \\ 0 & \sin(a) & \cos(a) \end{pmatrix} \\
Ry(a) &= \begin{pmatrix} \cos(a) & 0 & \sin(a) \\ 0 & 1 & 0 \\ -\sin(a) & 0 & \cos(a) \end{pmatrix} \\
Rz(a) &= \begin{pmatrix} \cos(a) & -\sin(a) & 0 \\ \sin(a) & \cos(a) & 0 \\ 0 & 0 & 1 \end{pmatrix}
\end{align*}
\]

Rotation around Arbitrary Axis

The Rotate() method allows you to rotate around an arbitrary vector (not necessary a unit one) and returns the result.

```cpp
r.Rotate(TMath::Pi() / 3, TVector3(3, 4, 5));
```

It is possible to find a unit vector and an angle, which describe the same rotation as the current one:

```cpp
double_t angle;
TVector3 axis;
r.GetAngleAxis(angle, axis);
```

Rotation of Local Axes

The RotateAxes() method adds a rotation of local axes to the current rotation and returns the result:

```cpp
TVector3 newX(0, 1, 0);
TVector3 newY(0, 0, 1);
TVector3 newZ(1, 0, 0);
a.RotateAxes(newX, newY, newZ);
```

Methods ThetaX(), ThetaY(), ThetaZ(), PhiX(), PhiY(), PhiZ() return azimuth and polar angles of the rotated axes:

```cpp
double_t tx, ty, tz, px, py, pz;
tx = a.ThetaX();
... 
pz = a.PhiZ();
```

Inverse Rotation

```cpp
TRotation a, b;
... 
b = a.Inverse(); // b is inverse of a, a is unchanged
b = a.Invert(); // invert a and set b = a
```

Compound Rotations

The operator * has been implemented in a way that follows the mathematical notation of a product of the two matrices which describe the two consecutive rotations. Therefore the second rotation should be placed first:
Rotation of TVector3

The TRotation class provides an operator * which allows to express a rotation of a TVector3 analog to the mathematical notation:

\[
\begin{array}{c|ccc|c}
\text{x'} & xx & xy & xz & x \\
\text{y'} & yx & yy & yz & y \\
\text{z'} & zx & zy & zz & z \\
\end{array}
\]

You can also use the Transform() method or the operator *= of the TVector3 class:

```cpp
TVector3 v(1,1,1);  
v = r * v;
```

TLorentzVector

`TLorentzVector` is a general four-vector class, which can be used either for the description of position and time (x, y, z, t) or momentum and energy (px, py, pz, E).

Declaration

`TLorentzVector` has been implemented as a set of a `TVector3` and a `Double_t` variable. By default all components are initialized by zero.

For backward compatibility there are two constructors from a `Double_t` and `Float_t` C array.

Access to Components

There are two sets of access functions to the components of a `TLorentzVector`: `X()`, `Y()`, `Z()`, `T()` and `Px()`, `Py()`, `Pz()`, and `E()`. Both sets return the same values but the first set is more relevant for use where `TLorentzVector` describes a combination of position and time and the second set is more relevant where `TLorentzVector` describes momentum and energy:

```cpp
Double_t xx = v.X();  
...  
Double_t tt = v.T();  
Double_t px = v.Px();  
...  
Double_t ee = v.E();  
```

The components of `TLorentzVector` can also be accessed by index:

```cpp
xx = v(0);  or  xx = v[0];  
yy = v(1);  yy = v[1];  
zz = v(2);  zz = v[2];  
tt = v(3);  tt = v[3];  
```

You can use the `Vect()` method to get the vector component of `TLorentzVector`:

```cpp
TVector3 p = v.Vect();
```
For setting components there are two methods: `SetX()`, `SetPx()`, ...

v.SetX(1.); or v.SetPx(1.);

... or ...

v.SetE(1.);

To set more than one component by one call you can use the `SetVect()` function for the `TVector3` part of `SetXYZT()`, `SetPxPyPzE()`. For convenience there is also a `SetXYZM()`:

v.SetVect(TVector3(1,2,3));
v.SetVect3(x, y, z, t);

v.SetPxPyPzE(px, py, pz, e);

v.SetXYZM(x, y, z, m);

// v = (x, y, z, e = Sqrt(x*x+y*y+z*z+m*m))

**Vector Components in non-Cartesian Coordinates**

There are a couple of methods to get and set the `TVector3` part of the parameters in spherical coordinate systems:

```
Double_t m, theta, cost, phi, pp, pp2, pp2v2;
m = v.Rho();
t = v.Theta();
cost = v.CosTheta();
phi = v.Phi();
v.SetRho(10.);
v.SetTheta(TMath::Pi()*.3);
```

or get information about the r-coordinate in cylindrical systems:

```
Double_t pp, pp2, pp2v2;
pp = v.Perp(); // get transverse component
pp2 = v.Perp2(); // get transverse component squared
pp2v2 = v.Perp(v1); // get transverse component with respect to another vector
```

For convenience there are two more set functions:

```
SetPtEtaPhiE(pt, eta, phi, e); and
SetPtEtaPhiM(pt, eta, phi, m);
```

**Arithmetic and Comparison Operators**

The `TLorentzVector` class provides operators to add, subtract or compare four-vectors:

```
v3 = -v1;
v1 = v2 + v3;
v1 += v3;
v1 = v2 + v3;
v1 -= v3;
if (v1 == v2) {...}
if(v1 != v3) {...}
```

**Magnitude/Invariant mass, beta, gamma, scalar product**

The scalar product of two four-vectors is calculated with the (-,-,-,+) metric:

```
s = v1*v2 = t1*t2-x1*x2-y1*y2-z1*z2
```

The magnitude squared `mag2` of a four-vector is therefore:

```
mag2 = v*v = t*t-x*x-y*y-z*z
```

If `mag2` is negative `mag = -Sqrt(-mag*mag).

The methods are:

```
Double_t s,  s2;
s  = v1.Dot(v2);  // scalar product
s  = v1*v2;      // scalar product
s2 = v.Mag2(); or s2 = v.M2();
s  = v.Mag(); s = v.M();
```

Since in case of momentum and energy the magnitude has the meaning of invariant mass `TLorentzVector` provides the more meaningful aliases `M2()` and `M()`.

The methods `Beta()` and `Gamma()` returns beta and gamma = 1/Sqrt(1-beta*beta).

**Lorentz Boost**

A boost in a general direction can be parameterized with three parameters which can be taken as the components of a three vector b = (bx, by, bz).

With X = (x, y, z) and gamma = 1/Sqrt(1-beta*beta), an arbitrary active Lorentz boost transformation (from the rod frame to the original frame) can be written as:

```
x' = x + (gamma-1)/(beta*beta)*(b*x') * b + gamma * t' * b
   t' = gamma (t+b*bx).
```
The Boost() method performs a boost transformation from the rod frame to the original frame. BoostVector() returns a TVector3 of the spatial components divided by the time component:

```c++
TVector3 b;
v.Boost(bx, by, bz);
b = v.BoostVector();  // b=(x/t, y/t, z/t)
```

Rotations
There are four sets of functions to rotate the TVector3 component of a TLorentzVector:

**Rotation around Axes**
```c++
v.RotateX(TMath::Pi()/2.);
v.RotateY(.5);
v.RotateZ(.99);
```

**Rotation around an Arbitrary Axis**
```c++
v.Rotate(TMath::Pi()/4., v1);
```

Transformation from Rotated Frame
```c++
v.RotateUz(direction);  // direction must be a unit TVector3
```

by TRotation (see TRotation)
```c++
TRotation r;
v.Transform(r);  or  v *= r;  // v = r*v
```

Miscellaneous

**Angle Between Two Vectors**
```c++
Double_t a = v1.Angle(v2);  // get angle between v1 and v2
```

Light-cone Components
Methods Plus() and Minus() return the positive and negative light-cone components:
```c++
Double_t pcone = v.Plus();
Double_t mcone = v.Minus();
```

Transformation by TLorentzRotation
A general Lorentz transformation see class TLorentzRotation can be used by the Transform() method, the *=, or * operator of the TLorentzRotation class:

```c++
TLorentzRotation l;
v.Transform(l);
v = l*v;  or  v *= l;  // v = l*v
```

TLorentzRotation
The TLorentzRotation class describes Lorentz transformations including Lorentz boosts and rotations (see TRotation)

```c++
lambda = |
| xx  xy  xz  xt |
| yx  yy  yz  yt |
| zx  zy  zz  zt |
| tx  ty  tz  tt |
```

Declaration
By default it is initialized to the identity matrix, but it may also be initialized by an other TLorentzRotation, by a pure TRotation or by a boost:

```c++
TLorentzRotation l;  // l is initialized as identity
TLorentzRotation m(l);  // m = l
TRotation r;
TLorentzRotation lr(r);
TLorentzRotation lb1(bx, by, bz);
TLorentzRotation lb2(b);
```

The Matrix for a Lorentz boosts is:

```c++
| 1+gamma'*bx*bx  gamma'*bx*by  gamma'*bx*bz  gamma*bx |
| gamma'*bx*by  1+gamma'*by*by  gamma'*by*bz  gamma*by |
| gamma'*bx*bz  gamma'*by*bz  1+gamma'*bz*bz  gamma*bz |
| gamma*bx       gamma*by       gamma*bz     gamma   |
```

with the boost vector b=(bx, by, bz) and gamma=1/\sqrt{1-beta*beta} and gamma'=\sqrt{(gamma-1)/beta*beta}. 

```
```
Access to the matrix Components/Comparisons

Access to the matrix components is possible with the methods XX(), XY() .. TT(), and with the operator (int,int):

```cpp
Double_t xx;
TLorentzRotation l;
xx = l.XX();  // gets the xx component
xx = l[0,0];  // gets the xx component
if (l==m) {...}  // test for equality
if (l.IsIdentity()) {...}  // test for identity
```

Transformations of a Lorentz Rotation

Compound transformations

There are four possibilities to find the product of two TLoerntzRotation transformations:

```cpp
TLorentzRotation a,b,c;
c = b*a;  // product
a *= b;  // a is unchanged
a = a.Transform(b)  // a=b*a then c=a
```

Lorentz boosts

```cpp
Double_t bx, by, bz;
TVector3 v(bx,by,bz);
TLorentzRotation l;
l.Boost(v);
l.Boost(bx,by,bz);
```

Rotations

```cpp
TVector3 axis;
l.RotateX(TMath::Pi());  // rotation around x-axis
l.Rotate(.5,axis);  // rotation around specified vector
```

Inverse transformation

The matrix for the inverse transformation of a TLoerntzRotation is as follows:

\[
\begin{pmatrix}
xx & xy & xz & -tx \\
xy & yy & yz & -ty \\
xz & yz & zz & -tz \\
-xt & -yt & -zt & tt
\end{pmatrix}
\]

To return the inverse transformation keeping the current one unchanged, use the method Inverse(). Invert() inverts the current transformation:

```cpp
TLorentzRotation:
ll = l2.Inverse();  // ll is inverse of l2, l2 unchanged
ll = l2.Invert();  // invert l2, then ll=l2
```

Transformation of a TLoerntzVector

To apply TLoerntzRotation to TLoerntzVector you can use either the VectorMultiplication() method or the * operator. You can also use the Transform() function and the *= operator of the TLoerntzVector class:

```cpp
TLorentzVector v;
TLorentzVector l;
...
v = l.VectorMultiplication(v);
v = l * v;
v.Transform(l);
v *= l;  // v = l*v
```

Physics Vector Example

To see an example of using physics vectors you can look at the test file. It is in $ROOTSYS/test/TestVectors.cxx. The vector classes are not loaded by default, and to run it, you will need to load libPhysics.so first:

```
root [] .L $ROOTSYS/lib/libPhysics.so
root [] .x TestVectors.cxx
```

To load the physics vector library in a ROOT application use:

```
gSystem->Load("libPhysics");
```

The example $ROOTSYS/test/TestVectors.cxx does not return much, especially if all went well, but when you look at the code you will find examples for many calls.
The Tutorials and Tests

Chapter 16: The Tutorials and Tests

This chapter is a guide to the examples that come with the installation of ROOT. They are located in two directories: $ROOTSYS/tutorials and $ROOTSYS/test.

$ROOTSYS/tutorials

The tutorials directory contains many example scripts. For the examples to work you must have write permission and you will need to execute hsimple.C first. If you do not have write permission in the $ROOTSYS/tutorials directory, copy the entire directory to your area.

The script hsimple.C displays a histogram as it is being filled, and creates a ROOT file used by the other examples. To execute it type:

```bash
cd $ROOTSYS/tutorials
root
```

Now execute demos.C, which brings up the button bar shown on the left. You can click on any button to execute an other example. To see the source, open the corresponding source file (for example fit1.C). Once you are done, and want to quit the ROOT session, you can do so by typing .q.

```bash
root [] .x demos.C
root [] .q
```

$ROOTSYS/test

The test directory contains a set of examples that represent all areas of the framework. When a new release is cut, the examples in this directory are compiled and run to test the new release's backward compatibility.

We see these source files:

- hsimple.cxx - Simple test program that creates and saves some histograms
- MainEvent.cxx - Simple test program that creates a ROOT Tree object and fills it with some simple structures but also with complete histograms. This program uses the files Event.cxx, EventCint.cxx and Event.h. An example of a procedure to link this program is in bind_Event. Note that the Makefile invokes the rootcint utility to generate the CINT interface EventCint.cxx.
- Event.cxx - Implementation for classes Event and Track
- minexam.cxx - Simple test program to test data fitting.
- v2collex.cxx - Example usage of the ROOT collection classes.
- tcollbm.cxx - Benchmarks of ROOT collection classes
- tstring.cxx - Example usage of the ROOT string class.
- vmatrix.cxx - Verification program for the TMatrix class.
- vvector.cxx - Verification program for the TVector class.
- vlazy.cxx - Verification program for lazy matrices.
- hvworld.cxx - Small program showing basic graphics.
- guitest.cxx - Example usage of the ROOT GUI classes.
- Hello.cxx - Dancing text example
- Aclock.cxx - Analog clock (a la X11 xclock)
- Tetris.cxx - The famous Tetris game (using ROOT basic graphics).
- stress.cxx - Important ROOT stress testing program.

The $ROOTSYS/test directory is a gold mine of root-wisdom nuggets, and we encourage you to explore and exploit it. These instructions will compile all programs in $ROOTSYS/test:

1. If you do not have write permission in the $ROOTSYS/test directory, copy the entire $ROOTSYS/test directory to your area.
2. The Makefile is a useful example of how ROOT applications are linked and built. Edit the Makefile to specify your architecture by changing the ARCH variable, for example, on an SGI machine type:

`ARCH = sgikcc`

3. Now compile all programs:

```
% gmake
```

This will build several applications and shared libraries. We are especially interested in Event, stress, and guitest.

**Event – An Example of a ROOT Application.**

Event is created by compiling MainEvent.cxx and Event.cxx. It creates a ROOT file with a tree and two histograms.

When running Event we have four optional arguments with defaults:

<table>
<thead>
<tr>
<th>Argument</th>
<th>Default</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>Number of Events (1 ... n)</td>
</tr>
<tr>
<td>2</td>
<td>Compression level:</td>
</tr>
<tr>
<td>3</td>
<td>Split or not Split</td>
</tr>
<tr>
<td>4</td>
<td>Fill</td>
</tr>
</tbody>
</table>

Floating point numbers are compressed differently because the gain when compressing them is about 20 - 30%. For other data types it is generally better and around 100%.

4. **Split or not Split**

0: only one single branch is created and the complete event is serialized in one single buffer

1: a branch per variable is created.

4. **Fill**

0: read the file

1: write the file, but don't fill the histograms

2: don't write, don't fill the histograms

10: fill the histograms, don't write the file

11: fill the histograms, write the file

20: read the file sequentially

25: read the file at random

**Effect of Compression on File Size and Write Times**

You may have noticed that a ROOT file has up to nine compression level, but here only levels 0, 1, and 2 are described. Compression levels above 2 are not competitive. They take up to much write time compared to the gain in file space.

Below are three runs of Event on a Pentium III 650 Mhz and the resulting file size and write and read times.

**No Compression**

```
> Event 400 0 1 1
400 events and 19153182 bytes processed.
RealTime=6.840000 seconds, CpuTime=3.560000 seconds
compression level=0, split=1, arg4=1
You write 2.800173 Mbytes/Realtime seconds
You write 5.380107 Mbytes/CpuTime seconds

ls -l Event.root
... 19752171 Feb 23 18:26 Event.root
```

We see the file size without compression is 19.75 MB, the write time is 6.84 seconds and the read time is 0.79 seconds.

**Compression = 1. event is compressed**

```
> Event 400 1 1 1
400 events and 19153182 bytes processed.
RealTime=6.440000 seconds, CpuTime=4.020000 seconds
compression level=1, split=1, arg4=1
You write 2.974096 Mbytes/Realtime seconds
You write 4.764473 Mbytes/CpuTime seconds

ls -l Event.root
... 17728188 Feb 23 18:28 Event.root
```

We see the file size 17.73, the write time was 6.44 seconds and the read time was 0.9 seconds.
The Tutorials and Tests February 2002 - version 3.2a

Compression = 2: Floating point numbers are compressed with level 1:

```
> Event 400 2 1 1
400 events and 19153182 bytes processed.
RealTime=11.340000 seconds, CpuTime=9.510000 seconds
compression level=2, split=1, arg4=1
You write 1.688993 Mbytes/Realtime seconds
You write 2.014004 Mbytes/Cputime seconds
```

```
ls -l Event.root
...     13783799 Feb 23 18:29 Event.root
```

```
> Event 400 2 1 20
400 events and 19153182 bytes processed.
RealTime=2.170000 seconds, CpuTime=2.170000 seconds
You read 8.826351 Mbytes/Realtime seconds
You read 8.826351 Mbytes/Cputime seconds
```

The file size is 13.78 MB, the write time is 11.34 seconds and the read time is 2.17 seconds.

This table summarizes the findings on the impact of compressions:

<table>
<thead>
<tr>
<th>Compression</th>
<th>File Size</th>
<th>Write Times</th>
<th>Read Times</th>
</tr>
</thead>
<tbody>
<tr>
<td>0</td>
<td>19.75 MB</td>
<td>6.84 sec</td>
<td>0.79 sec</td>
</tr>
<tr>
<td>1</td>
<td>17.73 MB</td>
<td>6.44 sec</td>
<td>0.90 sec</td>
</tr>
<tr>
<td>2</td>
<td>13.78 MB</td>
<td>11.34 sec</td>
<td>2.17 sec</td>
</tr>
</tbody>
</table>

Setting the Split Level

Split Level = 0:

Now we execute Event with the split parameter set to 0:

```
> Event 400 1 0 1
> root
TFile f("Event.root")
root >> TBrowser T
```

We notice that only one branch is visible (event). The individual data members of the Event object are no longer visible in the browser. They are contained in the event object on the event branch, because we specified no splitting.

Split Level = 1:

Setting the split level to 1 will create a branch for each data member in the Event object. We can see this by browsing the resulting files.

First we execute Event and set the split level to 1 and start the browser to examine the split tree:

```
> Event 400 1 1 1
> root
TFile f("Event.root")
root >> TBrowser browser
```

stress - Test and Benchmark

The executable stress is created by compiling stress.cxx. It completes sixteen tests covering the following capabilities of the ROOT framework.

1. Functions, Random Numbers, Histogram Fits
2. Size & compression factor of a ROOT file
3. Purge, Reuse of gaps in TFile
4. 2D Histograms, Functions, 2D Fits
5. Graphics & PostScript
6. Subdirectories in a ROOT file
7. TNtuple, Selections, TCut, TCutG, TEventList
8. Split and Compression modes for Trees
9. Analyze Event.root file of stress 8
10. Create 10 files starting from Event.root
11. Test chains of Trees using the 10 files
12. Compare histograms of test 9 and 11
13. Merging files of a chain
14. Check correct rebuild of Event.root in test 13
15. Divert Tree branches to separate files
16. CINT test (3 nested loops) with LHCb trigger

The program stress takes one argument, the number of events to process. The default is 1000 events. Be aware that executing stress with 1000 events will create several files consuming about 100 MB of disk space.
running stress with 30 events will consume about 20 MB. The disk space is released once stress is done.

There are two ways to run stress:

From the system prompt or from the ROOT prompt using the interpreter. Start ROOT with the batch mode option (-b) to suppress the graphic output.

```
> cd $ROOTSYS/test
> stress // default 1000 events
> stress 30 // test with 30 events

> root -b
root [] .x stress.cxx // default 1000 events
root [] .x stress.cxx (30) // test with 30 events
```

The output of stress includes a pass/fail conclusion for each test, the total number of bytes read and written, and the elapsed real and CPU time. It also calculates a performance index for your machine relative to a reference machine a DELL Inspiron 7500 (Pentium III 600 MHz) with 256 MB of memory and 18 GBs IDE disk in ROOTMARKS. Higher ROOTMARKS means better performance. The reference machine has 200 ROOTMARKS, so the sample run below with 53.7 ROOTMARKS is about four times slower than the reference machine.

Here is a sample run:

```
% root –b
root [] .x stress.cxx (30)
Test  1 : Functions, Random Numbers, Histogram Fits............. OK
Test  2 : Check size & compression factor of a Root file........ OK
Test  3 : Purge, Reuse of gaps in TFile......................... OK
Test  4 : Test of 2-d histograms, functions, 2-d fits.......... OK
Test  5 : Test graphics & PostScript........................... OK
Test  6 : Test subdirectories in a Root file................... OK
Test  7 : TTree, selections, TCut, TTree, TBranchList......... OK
Test  8 : Trees split and compression modes.................... OK
Test  9 : Analyze Event root file of stress 8................. OK
Test 10 : Create 10 files starting from Event.root............ OK
Test 11 : Test chains of Trees using the 10 files............. OK
Test 12 : Compare histograms of test 9 and 11.................. OK
Test 13 : Test merging files of a chain......................... OK
Test 14 : Check correct rebult of Event.root in test 13........ OK
Test 15 : Divert Tree branches to separate files............... OK
Test 16 : CINT test (3 nested loops) with LHCb trigger........ OK

The guitest – A Graphical User Interface

The guitest example, created by compiling guitest.cxx, tests and illustrates the use of the native GUI widgets such as cascading menus, dialog boxes, sliders and tab panels. It is a very useful example to study when designing a GUI. Below are some examples of the output of guitest, to run it type guitest at the system prompt in the $ROOTSYS/test directory.

We have included an entire chapter on this subject where we explore guitest in detail and use it to explain how to build our own ROOT application with a GUI (see Chapter Writing a Graphical User Interface).
17 Example Analysis

This chapter is an example of a typical physics analysis. Large data files are chained together and analyzed using the TSelector class.

Explanation

This script uses four large data sets from the H1 collaboration at DESY Hamburg. One can access these data sets (277 Mbytes) from the ROOT web site at: ftp://root.cern.ch/root/h1analysis/

The physics plots generated by this example cannot be produced using smaller data sets.

There are several ways to analyze data stored in a ROOT Tree

- Using TTree::Draw:
  This is very convenient and efficient for small tasks. A TTree::Draw call produces one histogram at the time. The histogram is automatically generated. The selection expression may be specified in the command line.

- Using the TTreeViewer:
  This is a graphical interface to TTree::Draw with the same functionality.

- Using the code generated by TTree::MakeClass:
  In this case, the user creates an instance of the analysis class. He has the control over the event loop and he can generate an unlimited number of histograms.

- Using the code generated by TTree::MakeSelector:
  Like for the code generated by TTree::MakeClass, the user can do complex analysis. However, he cannot control the event loop. The event loop is controlled by TTree::Process called by the user. This solution is illustrated by the code below. The advantage of this method is that it can be run in a parallel environment using PROOF (the Parallel Root Facility).

A chain of four files (originally converted from PAW ntuples) is used to illustrate the various ways to loop on ROOT data sets. Each contains a ROOT Tree named "h42". The class definition in hanalysish.h has been generated automatically by the ROOT utility TTree::MakeSelector using one of the files with the following statement:

```cpp
h42->MakeSelector("hianalysis");
```

This produces two files: hanalysish.h and hanalysish.C. A skeleton of hanalysish.C file is made for you to customize. The hanalysish class is derived from the ROOT class TSelector. The following members functions of hanalysish (i.e. TSelector) are called by the TTree::Process method.

- Begin: This function is called every time a loop over the tree starts. This is a convenient place to create your histograms.
- Notify(): This function is called at the first entry of a new tree in a chain.
- ProcessCut: This function is called at the beginning of each entry to return a flag true if the entry must be analyzed.
- ProcessFill: This function is called in the entry loop for all entries accepted by Select.
- Terminate: This function is called at the end of a loop on a TTree. This is a convenient place to draw and fit your histograms.

To use this program, try the following session.

First, turn the timer on to show the real and CPU time per command.

```bash
root[] gROOT->Time();
```

Step A: create a TChain with the four H1 data files. The chain can be created by executing this short script h1chain.C below. $H1 is a system symbol pointing to the H1 data directory.

```cpp
{
    TChain chain("h42");
    chain.Add("$H1/dstarmb.root");
    //21330730 bytes, 21920 events
    chain.Add("$H1/dstarp1a.root");
    //71464503 bytes, 73243 events
    chain.Add("$H1/dstarp1b.root");
    //83827959 bytes, 85597 events
    chain.Add("$H1/dstarp2.root");
    //100675234 bytes, 103053 events
}
```

Run the above script from the command line:

```bash
root[] .x h1chain.C
```

Step B: Now we have a directory containing the four data files. Since a TChain is a descendent of TTree we can call TChain::Process to loop on all events in the chain. The parameter to the TChain::Process method is the name of the file containing the created TSelector class (hianalysis.C).

```bash
root[] chain.Process("hianalysis.C")
```

Step C: Same as step A, but in addition fill the event list with selected entries. The event list is saved to a file "elists.root" by the
TSelector::Terminate method. To see the list of selected events, you can do elist->Print("all"). The selection function has selected 7525 events out of the 283813 events in the chain of files.

\[
\text{elistent->Print("all")}
\]

The selection function has selected 2.65 per cent of the events.

\[
\text{root[chain.Process("h1analysis.C","fillList")}
\]

**Step D:** Process only entries in the event list. The event list is read from the file in elist.root generated by step C.

\[
\text{root[chain.Process("h1analysis.C","useList")}
\]

**Step E:** The above steps have been executed with the interpreter. You can repeat the steps 2, 3, and 4 using ACLiC by replacing "h1analysis.C" by "h1analysis.C+" or "h1analysis.C++".

\[
\text{root[chain.Process("h1analysis+.C","useList")}
\]

**Step F:** If you want to see the differences between the interpreter speed and ACLiC speed start a new session, create the chain as in step 1, then execute:

\[
\text{root[chain.Process("h1analysis++.C","useList")}
\]

The commands executed with the four different methods B, C, D and E produce two canvases shown below:

---

**Script**

This is the h1analysis.C file that was generated by TTree::MakeSelector and then modified to perform the analysis.

```c
#include "h1analysis.h"
#include "TH2.h"
#include "TF1.h"
#include "TStyle.h"
#include "TCanvas.h"
#include "TLine.h"
#include "TEventList.h"

const Double_t dxbin = (0.17-0.13)/40; // Bin-width
const Double_t sigma = 0.0012;
TEventList *elist = 0;
Bool_t useList, fillList;
TH1F *hdmd;
TH2F *h2;

//_________________________________________________________
Double_t fdm5(Double_t *xx, Double_t *par)
{
    Double_t x = xx[0];
    if (x <= 0.13957) return 0;
    Double_t x3 = (x-par[3])*(x-par[3]);
    Double_t res = dxbin*(par[0]*TMath::Power(x-0.13957, par[1])
            x3/2/par[4]/par[4]));
    return res;
}
//_________________________________________________________
Double_t fdm2(Double_t *xx, Double_t *par)
{
    Double_t x = xx[0];
    if (x <= 0.13957) return 0;
    Double_t x3 = (x-0.1454)*(x-0.1454);
    Double_t res = dxbin*(par[0]*TMath::Power(x-0.13957, 0.25)
        + par[2] / 2.5066/sigma*TMath::Exp(
            x3/2/sigma/sigma));
    return res;
}
//_________________________________________________________
void h1analysis::Begin(TTree *tree)
{
    // function called before starting the event loop
    // -it performs some cleanup
    // -it creates histograms
    // -it sets some initialisation for the event list
    //initialize the Tree branch addresses
    Init(tree);
    //print the option specified in the Process function.
    TQString option = GetOption();

c2->Update();
TLine *line = new TLine(0,0,0,c2->GetUymax());
line->Draw();

// save the event list to a Root file if one was
// produced
if (fillList) {
    TFile efile("elist.root","recreate");
    elist->Write();
}
}
18 Networking

In this chapter, you will learn how to send data over the network using the ROOT socket classes.

Setting up a Connection

On the server side, we create a TServerSocket to wait for a connection request over the network. If the request is accepted, it returns a full-duplex socket. Once the connection is accepted, we can communicate to the client that we are ready to go by sending the string "go", and we can close the server socket.

```c
// server
TServerSocket *ss = new TServerSocket(9090, kTRUE);
TSocket *socket = ss->Accept();
socket->Send("go");
ss->Close();
```

On the client side, we create a socket and ask the socket to receive input.

```c
// client
TSocket *socket = new TSocket("localhost", 9090);
Char str[32];
socket->Recv(str,32);
```

Sending Objects over the Network

We have just established a connection and you just saw how to send and receive a string with the example "go". Now let's send a histogram.

To send an object (in our case on the client side) it has to derive from TObject because it uses the Streamers to fill a buffer that is then sent over the connection. On the receiving side, the Streamers are used to read the object from the message sent via the socket. For network communication, we have a specialized TBuffer, a descendant of TBuffer called TMessage. In the following example, we create a TMessage with the intention to store an object, hence the constant kMESS_OBJECT in the constructor. We create and fill the histogram and write it into the message. Then we call TSocket::Send to send the message with the histogram.

```c
... // create an object to be sent
TH1F *hpx = new TH1F("hpx","px distribution",100,-4,4);  
hpx->FillRandom("gaus",1000);  
// create a TMessage to send the object
TMessage message(kMESS_OBJECT);  
// write the histogram into the message buffer
message.WriteObject(hpx);  
// send the message
socket->Send(message);
...
```

On the receiving end (in our case the server side), we write a while loop to wait and receive a message with a histogram. Once we have a message, we call TMessage::ReadObject, which returns a pointer to TObject. We have to cast it to a TH1 pointer, and now we have a histogram. At the end of the loop, the message is deleted, and another one is created at the beginning.

```c
...  
while (1)  
{  
TMessage *message;  
socket->Recv(message);  
TH1 *h = (TH1*)message->ReadObject(message->GetClass());  
delete message;  
}
...  
```
Closing the Connection

Once we are done sending objects, we close the connection by closing the sockets at both ends.

... Socket->Close();
}

This diagram summarizes the steps we just covered:

<table>
<thead>
<tr>
<th>Server</th>
<th>Client</th>
</tr>
</thead>
<tbody>
<tr>
<td>TServerSocket *ss = new TServerSocket(9090, kTRUE);</td>
<td></td>
</tr>
<tr>
<td>TSocket *socket = ss-&gt;Accept();</td>
<td></td>
</tr>
<tr>

<tr>
<td>// send the message</td>
<td></td>
</tr>
<tr>
<td>socket-&gt;Send(message);</td>
<td></td>
</tr>
<tr>
<td>socket-&gt;Close();</td>
<td></td>
</tr>
</tbody>
</table>

A Server with Multiple Sockets

Chances are that your server has to be able to receive data from multiple clients. The class we need for this is TMonitor. It lets you add sockets and the TMonitor::Select method returns the socket with data waiting. Sockets can be added, removed, or enabled and disabled.

Here is an example of a server that has a TMonitor to manage multiple sockets:

```cpp
TServerSocket *ss = new TServerSocket(9090, kTRUE);
// Accept a connection and return a full-duplex
// communication socket.
TSocket *s0 = ss->Accept();
TSocket *s1 = ss->Accept();

// tell the clients to start
s0->Send("go 0");
s1->Send("go 1");

// Close the server socket (unless we will use it
// later to wait for another connection).
ss->Close();
TMonitor *mon = new TMonitor;
mon->Add(s0);
mon->Add(s1);

while (1) {
    TMessage *mess;
    TSocket *s;
    s = mon->Select();
    s->Recv(mess);
   ...
}
```

The full code for the example above is in $ROOTSYS/tutorials/hserver.cxx and $ROOTSYS/tutorials/hclient.cxx.
19 Writing a Graphical User Interface

The ROOT GUI classes support an extensive and rich set of widgets. The widgets classes depend only on the X11 and Xpm libraries, eliminating the need for any other GUI engine such as Motif or QT, and they have the Windows look and feel. They are based on Hector Peraza's Xclass'95 widget library.

Although powerful and quite feature rich, we are missing extensive documentation. This will come eventually but for the time being you will have to "program by example". We start with a short tutorial followed by few non-trivial examples that will show how to use the different widget classes.

The New ROOT GUI Classes

Features of the new GUI classes in a nutshell:

- Originally based on Xclass'95 widget library (under a Lesser GNU Public License)
  - A rich and complete set of widgets
  - Uses only X11 and Xpm (no Motif, Xaw, Xt, etc.)
  - Small (12000 lines of C++)
  - Win'95 look and feel
- All X11 calls abstracted using the "abstract" ROOT TGXW class
- Rewritten to use internally the ROOT container classes
- Completely scriptable via the C++ interpreter (fast prototyping)
- Full class documentation is generated automatically (as for all ROOT classes)

XClass'95

Here are some highlights of the XClass'95. Hector Peraza is the original author of the XClass'95 class library.

The Xclass'95 comes with a complete set of widgets. These include:

- Simple widgets, as labels and icons
- Push buttons, either with text or pix maps
- Check buttons
- Radio buttons
- Menu bars and popup menus

The widgets are shown in frames:
frame, composite frame, main frame, transient frame, group frame
And arranged by layout managers:
horizontal layout, vertical layout, row layout, list layout, tile layout, matrix layout, ...
Using a combination of layout hints:
left, center x, right, top, center y, bottom, expand x, expand y and fixed offsets
Event handling by messaging (as opposed to callbacks): in response to actions widgets send messages (SendMessage() to associated frames (ProcessMessage())

ROOT Integration

Replace all calls to X11 by calls to the ROOT abstract graphics base class TGXW. Currently, implementations of TGXW exist X11 (TGX11) and Win32 (TGWin32). Thanks to this single graphics interface, porting ROOT to a new platform (BeOS, Rhapsody, etc.) requires only the implementation of TGXW (and TSystem).

Abstract Graphics Base Class TGXW

```
  TGX11
   /    \
  TGWin32
   /    \
  TGClient
  Unix/Windows
```

```
  rootdisp
  Unix
```

```
  rootdisp
  Windows
```
Concrete implementations of TGXW are **TGX11**, for X Windows, **TGWin32** for Win95/NT. The TGXClient implementation provides a network interface allowing for remote display via the rootdisp servers.

**NOTE:** the ROOT GUI classes are for the time being only supported on Unix/X11 systems. Work on a Win32 port is in progress and coming shortly.

**Further changes:**

- Changed internals to use ROOT container classes, notably hash tables for fast lookup of frame and picture objects
- Added TObject inheritance to the few base classes to get access to the extended ROOT RTTI (type information and object inspection) and documentation system
- Conversion to the ROOT naming conventions to provide a homogeneous and consistent environment for the user

A Simple Example

The code that uses the GUI classes is written in bold font.

```cpp
#include <TROOT.h>
#include <TApplication.h>
#include <TGClient.h>
extern void InitGui();
VoidFuncPtr_t initfuncs[] = { InitGui, 0 };
TROOT root("GUI", "GUI test environment", initfuncs);
int main(int argc, char **argv)
{
  TApplication theApp("App", &argc, argv);
  MyMainFrame mainWin(gClient->GetRoot(), 200, 220);
  theApp.Run();
  return 0;
}

MyMainFrame

```
Laying out the Frame

MyMainFrame::MyMainFrame(const TGWindow *p, UInt_t w, UInt_t h): TGMainFrame(p, w, h)
{
    // Create a main frame with a number of different buttons.
    fButton1 = new TGTextButton(this, "&Version", 1);
    fButton1->SetCommand("printf \n\"This is ROOT version %s\n\", gROOT->GetVersion());
    fButton2 = new TGTextButton(this, "&Exit", 2);
    fButton2->SetCommand(".q");
    fPicBut = new TGPictureButton(this, gClient->GetPicture("world.xpm"), 3);
    fPicBut->SetCommand("printf \n\"hello world!\n\"; ");
    fChkBut = new TGCheckButton(this, "Check Button", 4);
    fRBut1 = new TGRadioButton(this, "Radio Button 1", 5);
    fRBut2 = new TGRadioButton(this, "Radio Button 2", 6);
    fLayout = new TGLayoutHints(kLHintsCenterX | kLHintsCenterY);
    AddFrame(fButton1, fLayout);
    AddFrame(fPicBut, fLayout);
    AddFrame(fButton2, fLayout);
    AddFrame(fChkBut, fLayout);
    AddFrame(fRBut1, fLayout);
    AddFrame(fRBut2, fLayout);
    Layout();
    SetWindowName("Button Example");
    SetIconName("Button Example");
    MapWindow();
}

Adding Actions

Bool_t MyMainFrame::ProcessMessage(Long_t msg, Long_t parm1, Long_t parm2)
{
    // Process events generated by the buttons in the frame.
    switch (GET_MSG(msg)) {
    case kC_COMMAND:
        switch (GET_SUBMSG(msg)) {
        case kCM_BUTTON:
            printf("text button id %ld pressed\n", parm1);
            break;
        case kCM_CHECKBUTTON:
            printf("check button id %ld pressed\n", parm1);
            break;
        case kCM_RADIOBUTTON:
            if (parm1 == 5)
                fRBut2->SetState(kButtonUp);
            if (parm1 == 6)
                fRBut1->SetState(kButtonUp);
            printf("radio button id %ld pressed\n", parm1);
            break;
        default:
            break;
        }
        break;
    default:
        break;
    }
    return kTRUE;
}

The Result

The Widgets in Detail

In this section we look at an example of using the widgets. The complete source code is in $ROOTSYS/test/guitest.C. Build the test directory with the appropriate makefile, and you will be able to run guitest. Here we present snippets of the code and the graphical output.
First the main program, which reveals that the functionality is in TestMainFrame.

```c
TROOT root("GUI", "GUI test environment");
int main(int argc, char **argv)
{
    TApplication theApp("App", &argc, argv);
    if (gROOT->IsBatch()) {
        fprintf(stderr, "%s: cannot run in batch mode\n", argv[0]);
        return 1;
    }
    TestMainFrame mainWindow(gClient->GetRoot(), 400, 220);
    theApp.Run();
    return 0;
}
```

TestMainFrame has two subframes (TGCompositeFrame), a canvas, a text entry field, a button, a menu bar, several popup menus, and layout hints. It has a public constructor, destructor and a ProcessMessage method to carry out the actions.

```c
class TestMainFrame : public TGMainFrame {
private:
    TGCompositeFrame   *fStatusFrame;
    TGCanvas           *fCanvasWindow;
    TGCompositeFrame   *fContainer;
    TGTextEntry        *fTestText;
    TGButton           *fTestButton;
    TGMenuBar          *fMenuBar;
    TGPopupMenu        *fMenuFile, *fMenuTest, *fMenuHelp;
    TGPopupMenu        *fCascadeMenu,
                         *fCascade1Menu, *fCascade2Menu;
    TGLayoutHints      *fMenuBarLayout, *fMenuBarItemLayout,
                         *fMenuBarHelpLayout;
public:
    TestMainFrame(const TGWindow *p, UInt_t w, UInt_t h);
    virtual ~TestMainFrame();
    virtual void CloseWindow();
    virtual Bool_t ProcessMessage(Long_t msg, Long_t parm1,
                                   Long_t parm2);
};
```

Example: Widgets and the Interpreter

The script $ROOTSYS/tutorials/dialogs.C shows how the widgets can be used from the interpreter.

RQuant Example

This is an example of extensive use of the ROOT GUI classes. I include only a picture here, for the curious the full documentation or RQuant can be found at: [http://www.smartquant.com/welcome.html](http://www.smartquant.com/welcome.html)

  An Example of an elaborate ROOT GUI application.

The class descriptions on the ROOT website have been generated automatically by ROOT itself with the THtml class. With it, you can automatically generate (and update) a reference guide for your ROOT classes. Please read the THtml class description and the paragraph on Coding Conventions.

The following illustrates how to generate an html class description using the MakeClass method. In this example class name is TBRIK.

```c++
root[] THtml html; // instanciate a THtml object
root[] html->MakeClass("TBRIK")
```

How to generate html code for all classes, including an index.

```c++
root[] html->MakeAll();
```

This example shows how to convert a script to html, including the generation of a "gif" file produced by the script. First execute the script.

```c++
root[] .x htmlex.C
```

Invoke the TSystem class to execute a shell script. Here we call the "xpick" program to capture the graphics window into a gif file.

```c++
root[] gSystem->Exec("xpick html/gif/shapes.gif")
```

Convert this script into html.

```c++
root[] html->Convert("htmlex.C","Auto HTML document generation")
```

For more details see the documentation of the class THtml.
Building on the experience gained from the implementation and operation of the PIAF system we have developed the parallel ROOT facility, PROOF. The main problems with PIAF were because its proper parallel operation depended on a cluster of homogenous equally performing and equally loaded machines. Due to PIAF's simplistic portioning of a job in N equal parts, where N is the number of processors, the overall performance was governed by the slowest node. The running of a PIAF cluster was an expensive operation since it required a cluster dedicated solely to PIAF. The cluster could not be used for other types of jobs without destroying the PIAF performance.

In the implementation of PROOF, we made the slave servers the active components that ask the master server for new work whenever they are ready. In the scheme the parallel processing performance is a function of the duration of each small job, packet, and the networking bandwidth and latency. Since the bandwidth and latency of a networked cluster are fixed the main tunable parameter in this scheme is the packet size. If the packet size is too small the parallelism will be destroyed by the communication overhead caused by the many packets sent over the network between the master and the slave servers. If the packet size is too large, the effect of the difference in performance of each node is not evened out sufficiently.

Another very important factor is the location of the data. In most cases, we want to analyze a large number of data files, which are distributed over the different nodes of the cluster. To group these files together we use a chain. A chain provides a single logical view of the many physical files. To optimize performance by preventing huge amounts of data being transferred over the network via NFS or any other means when analyzing a chain, we make sure that each slave server is assigned a packet, which is local to the node. Only when a slave has processed all its local data will it get packets assigned that cause remote access. A packet is a simple data structure of two numbers: begin event and number of events. The master server generates a packet when asked for by a slave server, taking into account the time it took to process the previous packet and which files in the chain are local to the slave server. The master keeps a list of all generated packets per slave, so in case a slave dies during processing, all its packets can be reprocessed by the left over slaves.
Threads

A thread is an independent flow of control that operates within the same address space as other independent flows of controls within a process. In most UNIX systems, thread and process characteristics are grouped into a single entity called a process. Sometimes, threads are called "lightweight processes". Note: This introduction is adapted from the AIX 4.3 Programmer's Manual.

Threads and Processes

In traditional single-threaded process systems, a process has a set of properties. In multi-threaded systems, these properties are divided between processes and threads.

Process Properties

A process in a multi-threaded system is the changeable entity. It must be considered as an execution frame. It has all traditional process attributes, such as:

- Process ID, process group ID, user ID, and group ID
- Environment
- Working directory

A process also provides a common address space and common system resources:

- File descriptors
- Signal actions
- Shared libraries
- Inter-process communication tools (such as message queues, pipes, semaphores, or shared memory)

Thread Properties

A thread is the schedulable entity. It has only those properties that are required to ensure its independent flow of control. These include the following properties:

- Stack
- Scheduling properties (such as policy or priority)
- Set of pending and blocked signals
- Some thread-specific data (TSD)

An example of thread-specific data is the error indicator, errno. In multi-threaded systems, errno is no longer a global variable, but usually a subroutine returning a thread-specific errno value. Some other systems may provide other implementations of errno.

With respect to ROOT, a thread specific data is for example the gPad pointer, which is treated in a different way, whether it is accessed from any thread or the main thread.

Threads within a process must not be considered as a group of processes (even though in Linux each thread receives an own process id, so that it can be scheduled by the kernel scheduler). All threads share the same address space. This means that two pointers having the same value in two threads refer to the same data. Also, if any thread changes one of the shared system resources, all threads within the process are affected. For example, if a thread closes a file, the file is closed for all threads.

The Initial Thread

When a process is created, one thread is automatically created. This thread is called the initial thread or the main thread. The initial thread executes the main routine in multi-threaded programs.

Note: At the end of this chapter is a glossary of thread specific terms

Implementation of Threads in ROOT

The TThread class has been developed to provide a platform independent interface to threads for ROOT.

Installation

For the time being, it is still necessary to compile a threaded version of ROOT to enable some very special treatments of the canvas operations. We hope that this will become the default later.

To compile ROOT, just do (for example on a debian Linux):

```
./configure linuxdeb2 --with-thread=/usr/lib/libpthread.so
gmake depend
gmake
```
This configures and builds ROOT using /usr/lib/libpthread.so as the Pthread library, and defines R__THREAD. This enables the thread specific treatment of gPad, and creates $ROOTSYS/lib/libThread.so.

Note: The parameter linuxdeb2 has to be replaced with the appropriate ROOT keyword for your platform.

Classes

TThread
This class implements threads. The platform dependent implementation is in the TThreadImp class and its descendant classes (e.g. TPosixThread).

TMutex
This class implements mutex locks. A mutex is a mutually exclusive lock. The platform dependent implementation is in the TMutexImp class and its descendant classes (e.g. TPosixMutex).

TCondition
This class implements a condition variable. Use a condition variable to signal threads. The platform dependent implementation is in the TConditionImp class and its descendant classes (e.g. TPosixCondition).

TSemaphore
This class implements a counting semaphore. Use a semaphore to synchronize threads. The platform dependent implementation is in the TMutexImp and TConditionImp classes.

TThread for Pedestrians
To run a thread in ROOT, follow these steps:

Initialization:
Add these lines to your rootlogon.C:

```c
{
  // The next line may be unnecessary on some platforms
  gSystem->Load("/usr/lib/libpthread.so");
  gSystem->Load("$ROOTSYS/lib/libThread.so");
  
}
```

This loads the library with the TThread class and the pthread specific implementation file for Posix threads.

Coding:
Define a function (e.g. void* UserFun(void* UserArgs)) that should run as a thread. The code for the examples is at the web site of the authors (Jörn Adamczewski, Marc Hemberger). After downloading the code from this site, you can follow the example below.

www-linux.gsi.de/~go4/HOWTOthreads/howtothreadsbody.html#tth_sEc6

Loading:
Start an interactive ROOT session
Load the shared library:

```c
root [] gSystem->Load("mhs3.so");
```

Or

```c
root [] gSystem->Load("CalcPiThread.so");
```

Creating:
Create a thread instance (see also example RunMhs3.C or RunPi.C) with:

```c
root [] TThread *th = new TThread(UserFun, UserArgs);
```

When called from the interpreter, this gives the name "UserFun" to the thread. This name can be used to retrieve the thread later. However, when called from compiled code, this method does not give any name to the thread. So give a name to the thread in compiled use:

```c
root [] TThread *th = new TThread("MyThread", UserFun, UserArgs);
```

You can pass arguments to the thread function using the UserArgs-pointer.

When you want to start a method of a class as a thread, you have to give the pointer to the class instance as UserArgs.

Running:

```c
root [] th->Run();
root [] TThread::Ps(); // like UNIX ps command;
```

With the mhs3 example, you should be able to see a canvas with two pads on it. Both pads keep histograms updated and filled by three different threads.

With the calcPi example, you should be able to see two threads calculating Pi with the given number of intervals as precision.
**TThread in More Detail**

CINT is not thread safe yet, and it will block the execution of the threads until it has finished executing.

**Asynchronous Actions**

Different threads can work simultaneously with the same object. Some actions can be dangerous. For example, when two threads create a histogram object, ROOT allocates memory and puts them to the same collection. If it happens at the same time, the results are undetermined. To avoid this problem, the user has to synchronize these actions with:

```c
TThread::Lock()  // Locking the following part of code
...              // Create an object, etc...
TThread::UnLock() // Unlocking
```

The code between `Lock()` and `UnLock()` will be performed uninterrupted. No other threads can perform actions or access objects/collections while it is being executed. The `TThread::Lock()` and `TThread::UnLock()` methods internally use a global `TMutex` instance for locking. The user may also define his own `TMutex` instance and may locally protect his asynchronous actions by calling `MyMutex.Lock()` and `MyMutex.UnLock()`.

**Synchronous Actions: TCondition**

To synchronize the actions of different threads you can use the `TCondition` class, which provides a signaling mechanism.

The `TCondition` instance must be accessible by all threads that need to use it, i.e. it should be a global object (or a member of the class which owns the threaded methods, see below). To create a `TCondition` object, a `TMutex` instance is required for the `Wait` and `TimedWait` locking methods. One can pass the address of an external mutex to the `TCondition` constructor:

```c
TMutex MyMutex;
TCondition MyCondition(MyMutex);
```

If zero is passed, `TCondition` creates and uses its own internal mutex:

```c
TCondition MyCondition(0);
```

You can now use the following methods of synchronization:

- If several threads wait for the signal from the same `TCondition` `MyCondition`, `at MyCondition.Signal()` only one thread will react; to activate a further thread another `MyCondition.Signal()` is required, etc.
- If several threads wait for the signal from the same `TCondition` `MyCondition`, at `MyCondition.Broadcast()` all threads waiting for `MyCondition` are activated at once.

In some tests of `MyCondition` using an internal mutex, `Broadcast()` activated only one thread (probably depending whether `MyCondition` had been signaled before).

- `MyCondition.TimedWait(secs, nanosecs)` waits for `MyCondition` until the absolute time in seconds and nanoseconds since beginning of the epoch (January, 1st, 1970) is reached; to use relative timeouts `"delta"`, it is required to calculate the absolute time at the beginning of waiting `"now"`, for example:

```c
Ulong_t now,then,delta;  // seconds
TDatime myTime;          // root daytime class
myTime.Set();            // myTime set to "now"
then=myTime.Convert();   // to seconds since 1970
wait=MyCondition.TimedWait(then,0); // waiting
```

Return value `wait` of `MyCondition.TimedWait` should be 0, if `MyCondition.Signal()` was received, and should be nonzero, if timeout was reached.

The conditions example shows how three threaded functions are synchronized using `TCondition`: a ROOT script `condstart.C` starts the threads, which are defined in a shared library (`conditions.cxx`, `conditions.h`).

**Xlib connections**

Usually Xlib is not thread safe. This means that calls to the X could fail, when it receives X-messages from different threads. The actual result depends strongly on which version of Xlib has been installed on your system. The only thing we can do here within ROOT is calling a special function `XInitThreads()` (which is part of the Xlib), which should (!) prepare the Xlib for the usage with threads.

To avoid further problems within ROOT some redefinition of the `gPad` pointer was done (that's the main reason for the recompilation). When a thread creates a `TCanvas`, this object is actually created in the main thread, this
should be transparent to the user. Actions on the canvas are controlled via a function, which returns a pointer to either thread specific data (TSD) or the main thread pointer. This mechanism works currently only for gPad and will soon be implemented for other global Objects as e.g. gVirtualX, gDirectory, gFile.

Canceling a TThread

Canceling of a thread is a rather dangerous action. In TThread canceling is forbidden by default. The user can change this default by calling TThread::SetCancelOn(). There are two cancellation modes:

**Deferred**
Set by TThread::SetCancelDeferred() (default): When the user knows safe places in his code where a thread can be canceled without risk for the rest of the system, he can define these points by invoking TThread::CancelPoint(). Then, if a thread is canceled, the cancellation is deferred up to the call of TThread::CancelPoint() and then the thread is canceled safely. There are some default cancel points for pthreads implementation, e.g. any call of TCondition::Wait(), TCondition::TimedWait(), TThread::Join().

**Asynchronous**
Set by TThread::SetCancelAsynchronous(): If the user is sure that his application is cancel safe, he could:

```c
TThread::SetCancelDeferred();
TThread::SetCancelOn();
// Now cancellation in any point is allowed.
...
...
// Return to default
TThread::SetCancelOff();
TThread::SetCancelDeferred();
```

To cancel a thread TThread* th call:

```c
Th->Kill();
```

To cancel by thread name:

```c
TThread::Kill(name);
```

To cancel a thread by ID:

```c
TThread::Kill(tid);
```

To cancel a thread and delete th when cancel finished:

```c
Th->Delete();
```

Deleting of the thread instance by the operator delete is dangerous. Use th->Delete() instead. C++ delete is safe only if thread is not running.

Often during the canceling, some clean up actions must be taken. To define clean up functions use:

```c
void UserCleanUp(void *arg){
    // here the user cleanup is done
    ...
}
TThread::CleanUpPush(&UserCleanUp,arg);
    // push user function into cleanup stack
    // "last in, first out"
TThread::CleanUpPop(1);
    // pop user function out of stack
    // and execute it,
    // thread resumes after this call
TThread::CleanUpPop(0);
    // pop user function out of stack
    // _without_ executing it
```

Note: CleanUpPush and CleanUpPop should be used as corresponding pairs like brackets; unlike pthreads cleanup stack (which is not implemented here), TThread does not force this usage.

**Finishing thread**

When a thread returns from a user function the thread is finished. It also can be finished by TThread::Exit(). Then, in case of pthread-detached mode, the thread vanishes completely.

By default, on finishing TThread executes the most recent cleanup function (CleanUpPop(1) is called automatically once).

**Advanced TThread: Launching a Method in a Thread**

Consider a class Myclass with a member function void* Myclass::Thread0(void* arg) that shall be launched as a thread. To start Thread0 as a TThread, class Myclass may provide a method:

```c
Int_t Myclass::Threadstart(){
    if(!mTh){
        mTh = new TThread("memberfunction",
            (void(*)(void*))&Thread0,
            (void*) this);
        mTh->Run();
        return 0;
    }
    return 1;
}
```

Here mTh is a TThread* pointer which is member of Myclass and should be initialized to 0 in the constructor. The TThread constructor is called as when we used a plain C function above, except for the following two differences.

First, the member function Thread0 requires an explicit cast to (void*)(void*). This may cause an annoying but harmless compiler warning:
Strictly speaking, Thread0 must be a static member function to be called from a thread. Some compilers, for example gcc version 2.95.2, may not allow the (void*) (void*) cast and just stop if Thread0 is not static. On the other hand, if Thread0 is static, no compiler warnings are generated at all.

Because the ‘this’ pointer is passed in ‘arg’ in the call to Thread0(void *arg), you have access to the instance of the class even if Thread0 is static. Using the ‘this’ pointer, non static members can still be read and written from Thread0, as long as you have provided Getter and Setter methods for these members.

For example:

```c
Bool_t state = arg->GetRunStatus();
arg->SetRunStatus(state);
```

Second, the pointer to the current instance of MyClass, i.e. (void*) this, has to be passed as first argument of the threaded function Thread0 (C++ member functions internally expect the this pointer as first argument to have access to class members of the same instance). pthreads are made for simple C functions and do not know about Thread0 being a member function of a class. Thus, you have to pass this information by hand, if you want to access all members of the MyClass instance from the Thread0 function.

Note: Method Thread0 cannot be a virtual member function, since the cast of Thread0 to void(*) in the TThread constructor may raise problems with C++ virtual function table. However, Thread0 may call another virtual member function virtual void MyClass::Func01() which then can be overridden in a derived class of MyClass. (See example TMhs3).

Class MyClass may also provide a method to stop the running thread:

```c
Int_t MyClass::ThreadStop()
{ 
 if(mTh){
 TThread::Delete(mTh);
 delete mTh;
 mTh=0;
 return 0;
 }
 return 1;
}
```

Example TMhs3: Class TThreadframe (TThreadframe.h, TThreadframe.cxx) is a simple example of a framework class managing up to four threaded methods. Class TMhs3 (TMhs3.h, TMhs3.cxx) inherits from this base class, showing the mhs3 example 8.1 (mhs3.h, mhs3.cxx) within a class.

The Makefile of this example builds the shared libraries libTThreadframe.so and libTMhs3.so. These are either loaded or executed by the ROOT script TMhs3demo.C, or are linked against an executable: TMhs3run.cxx.

**Known Problems**

Parts of the ROOT framework, like the interpreter, are not yet thread-safe. Therefore, you should use this package with caution. If you restrict your threads to distinct and ‘simple’ duties, you will be able to benefit from their use.

The TThread class is available on all platforms, which provide a POSIX compliant thread implementation. On Linux, Xavier Leroy’s Linux Threads implementation is widely used, but the TThread implementation should be usable on all platforms that provide pthread.

Linux Xlib on SMP machines is not yet thread-safe. This may cause crashes during threaded graphics operations; this problem is independent of ROOT.

Object instantiation: there is no implicit locking mechanism for memory allocation and global ROOT lists. The user has to explicitly protect his code when using them.

**Glossary**

The following glossary is adapted from the description of the Rogue Wave Threads.h++ package.

**Process**

A process is a program that is loaded into memory and prepared for execution. Each process has a private address space. Processes begin with a single thread.

**Thread**

A thread of control, or more simply, a thread, is a sequence of instructions being executed in a program. A thread has a program counter and a private stack to keep track of local variables and return addresses. A multithreaded process is associated with one or more threads. Threads execute independently. All threads in a given process share the private address space of that process.

**Concurrency**

Concurrency exists when at least two threads are in progress at the same time. A system with only a single processor can support concurrency by switching execution contexts among multiple threads.

**Parallelism**

Parallelism arises when at least two threads are executing simultaneously. This requires a system with multiple processors. Parallelism implies concurrency, but not vice-versa.

**Reentrant**

A function is reentrant if it will behave correctly even if a thread of execution enters the function while one or more threads are already executing within the function. These could be the same thread, in the case of recursion, or different threads, in the case of concurrency.
Thread-specific data
Thread-specific data (TSD) is also known as thread-local storage (TLS). Normally, any data that has lifetime beyond the local variables on the thread’s private stack are shared among all threads within the process. Thread-specific data is a form of static or global data that is maintained on a per-thread basis. That is, each thread gets its own private copy of the data.

Synchronization
Left to their own devices, threads execute independently. Synchronization is the work that must be done when there are, in fact, interdependencies that require some form of communication among threads. Synchronization tools include mutexes, semaphores, condition variables, and other variations on locking.

Critical Section
A critical section is a section of code that accesses a non-sharable resource. To ensure correct code, only one thread at a time may execute in a critical section. In other words, the section is not reentrant.

Mutex
A mutex, or mutual exclusion lock, is a synchronization object with two states locked and unlocked. A mutex is usually used to ensure that only one thread at a time executes some critical section of code. Before entering a critical section, a thread will attempt to lock the mutex, which guards that section. If the mutex is already locked, the thread will block until the mutex is unlocked, at which time it will lock the mutex, execute the critical section, and unlock the mutex upon leaving the critical section.

Semaphore
A semaphore is a synchronization mechanism that starts out initialized to some positive value. A thread may ask to wait on a semaphore in which case the thread blocks until the value of the semaphore is positive. At that time the semaphore count is decremented and the thread continues. When a thread releases semaphore, the semaphore count is incremented. Counting semaphores are useful for coordinating access to a limited pool of some resource.

Readers/Writer Lock
A multiple-readers, single-writer lock is one that allows simultaneous read access by many threads while restricting write access to only one thread at a time. When any thread holds the lock for reading, other threads can also acquire the lock reading. If one thread holds the lock for writing, or is waiting to acquire the lock for writing, other threads must wait to acquire the lock for either reading or writing.

Condition Variable
Use a condition variable in conjunction with a mutex lock to automatically block threads until a particular condition is true.

Multithread safe levels
A possible classification scheme to describe thread-safety of libraries:
- All public and protected functions are reentrant. The library provides protection against multiple threads trying to modify static and global data used within a library. The developer must explicitly lock access to objects shared between threads. No other thread can write to a locked object unless it is unlocked. The developer needs to lock local objects. The spirit, if not the letter of this definition, requires the user of the library only to be familiar with the semantic content of the objects in use. Locking access to objects that are being shared due to extra-semantic details of implementation (for example, copy-on-write) should remain the responsibility of the library.
- All public and protected functions are reentrant. The library provides protection against multiple threads trying to modify static and global data used within the library. The preferred way of providing this protection is to use mutex locks. The library also locks an object before writing to it. The developer is not required to explicitly lock or unlock a class object (static, global or local) to perform a single operation on the object. Note that even multithread safe level II hardly relieves the user of the library from the burden of locking.

Deadlock
A thread suffers from deadlock if it is blocked waiting for a condition that will never occur. Typically, this occurs when one thread needs to access a resource that is already locked by another thread, and that other thread is trying to access a resource that has already been locked by the first thread. In this situation, neither thread is able to progress; they are deadlocked.

Multiprocessor
A multiprocessor is a hardware system with multiple processors or multiple, simultaneous execution units.
List of Example files

Here is a list of the examples that you can find on the thread authors' web site (Jörn Adamczewski, Marc Hemberger) at:
www-linux.gsi.de/~go4/HOWTOthreads/howtothreadsbody.html#tth_sEcv

Example mhs3
- Makefile.mhs3
- mhs3.h
- mhs3LinkDef.h
- mhs3.cxx
- rootlogon.C
- RunMhs3.C

Example conditions
- Makefile.conditions
- conditions.h
- conditionsLinkDef.h
- conditions.cxx
- condstart.C

Example TMhs3
- Makefile.TMhs3
- TThreadframe.h
- TThreadframeLinkDef.h
- TThreadframe.cxx
- TMhs3.h
- TMhs3LinkDef.h
- TMhs3.cxx
- TMhs3run.cxx
- TMhs3demo.C

Example CalcPiThread
- Makefile.CalcPiThread
- CalcPiThread.h
- CalcPiThreadLinkDef.h
- CalcPiThread.cxx
- rootlogon.C
- RunPi.C
Appendix A: Install and Build ROOT

ROOT Copyright and Licensing Agreement:
This is a reprint of the copyright and licensing agreement of ROOT:
Copyright (C) 1995-2000, René Brun and Fons Rademakers. All rights reserved.

ROOT Software Terms and Conditions
The authors hereby grant permission to use, copy, and distribute this software and its documentation for any purpose, provided that existing copyright notices are retained in all copies and that this notice is included verbatim in any distributions. Additionally, the authors grant permission to modify this software and its documentation for any purpose, provided that such modifications are not distributed without the explicit consent of the authors and that existing copyright notices are retained in all copies. Users of the software are asked to feed back problems, benefits, and/or suggestions about the software to the ROOT Development Team (rootdev@root.cern.ch). Support for this software - fixing of bugs, incorporation of new features - is done on a best effort basis. All bug fixes and enhancements will be made available under the same terms and conditions as the original software,

IN NO EVENT SHALL THE AUTHORS OR DISTRIBUTORS BE LIABLE TO ANY PARTY FOR DIRECT, INDIRECT, SPECIAL, INCIDENTAL, OR CONSEQUENTIAL DAMAGES ARISING OUT OF THE USE OF THIS SOFTWARE, ITS DOCUMENTATION, OR ANY DERIVATIVES THEREOF, EVEN IF THE AUTHORS HAVE BEEN ADVISED OF THE POSSIBILITY OF SUCH DAMAGE.

THE AUTHORS AND DISTRIBUTORS SPECIFICALLY DISCLAIM ANY WARRANTIES, INCLUDING, BUT NOT LIMITED TO, THE IMPLIED WARRANTIES OF MERCHANTABILITY, FITNESS FOR A PARTICULAR PURPOSE, AND NON-INFRINGEMENT. THIS SOFTWARE IS PROVIDED ON AN "AS IS" BASIS, AND THE AUTHORS AND DISTRIBUTORS HAVE NO OBLIGATION TO PROVIDE MAINTENANCE, SUPPORT, UPDATES, ENHANCEMENTS, OR MODIFICATIONS.

Installing ROOT
To install ROOT you will need to go to the ROOT website at:
http://root.cern.ch/root/Availability.html
You have a choice to download the binaries or the source. The source is quicker to transfer since it is only 3.4 MB, but you will need to compile and link it. The binaries range from 7.4 MB to 11 MB depending on the target platform.

Choosing a Version
The ROOT developers follow the principle of "release early and release often", however a very large portion of a user base requires a stable product therefore generally three versions of the system is available for download – new, old and pro:

- **The new** version evolves quickly, with weekly or bi-weekly releases. Use this to get access to the latest and greatest, but it may not be stable. By trying out the new version you can help us converge quickly to a stable version that can then become the new pro version. If you are a new user we would advice you to try the new version.

- **The pro** (production) version is a version we feel comfortable with to exposing to a large audience for serious work. The change rate of this version is much lower than for the new version, it is about 3 to 6 months.

- **The old** version is the previous pro version that people might need for some time before switching the new pro version. The old change rate is the same as for pro.

Supported Platforms
For each of the three versions the full source is available for these platforms. Precompiled binaries are also provided for most of them:

- Intel x86 Linux (g++, egcs and KAI/KCC)
- Intel Itanium Linux (g++)
- HP HP-UX 10.x (HP CC and aCC, egcs1.1 C++ compilers)
- IBM AIX 4.1 (xlc compiler and egcs1.2)
- Sun Solaris for SPARC (SUN C++ compiler and egcs)
- Sun Solaris for x86 (SUN C++ compiler)
- Sun Solaris for x86 KAI/KCC
- Compaq Alpha OSF (egcs1.2 and DEC/CXX)
- Compaq Alpha Linux (egcs1.2)
- SGI Irix (g++, KAI/KCC and SGI C++ compiler)
- Windows NT and Windows95 (Visual C++ compiler)
- Mac MkLinux and Linux PPC (g++)
- Hitachi HT-UX (egcs)
- LynxOS
- MacOS (CodeWarrior, no graphics)
Installing Precompiled Binaries

The binaries are available for downloading from
root.cern.ch/root/Availability.html.

Once downloaded you need to unzip and de-tar the file. For example, if you have downloaded ROOT v2.25 for HPUX:

```
% gunzip root_v2.25.00.HP-UX.B.10.20.tar.gz
% tar xvf root_v2.25.00.HP-UX.B.10.20.tar
```

This will create the directory root. Before getting started read the file README/README. Also, read the Introduction chapter for an explanation of the directory structure.

Installing the Source

You have a choice to download a compressed (tar ball) file containing the source, or you can login to the source code change control (CVS) system and check out the most recent source. The compressed file is a one time only choice; every time you would like to upgrade you will need to download the entire new version. Choosing the CVS option will allow you to get changes as they are submitted by the developers and you can stay up to date.

**Installing and Building the source from a compressed file**

To install the ROOT source you can download the tar file containing all the source files from the ROOT website. The first thing you should do is to get the latest version as a tar file. Unpack the source tar file, this creates directory 'root':

```
% tar zxfv root_v2.25.xx.source.tar.gz
```

Set `ROOTSYS` to the directory where you want root to be installed:

```
% export ROOTSYS=<path>/root
```

Now type the build commands:

```
% cd root
% ./configure --help
% ./configure <target>
% gmake
% gmake install
```

Add `$$ROOTSYS/bin` to `PATH` and `$$ROOTSYS/lib` to `LD_LIBRARY_PATH`:

```
% export PATH=$$ROOTSYS/bin:$PATH
% export LD_LIBRARY_PATH=$$ROOTSYS/lib:$LD_LIBRARY_PATH
```

Try running `root`:

```
% root
```

It is also possible to setup and build ROOT in a fixed location. Please check README/INSTALL for more a detailed description of this procedure.

Target directory

By default, ROOT will be built in the `$ROOTSYS` directory. In that case the whole system (binaries, sources, tutorials, etc.) will be located under the `$ROOTSYS` directory.

Makefile targets

The Makefile is documented in details in the README/BUILDSYSTEM file. It explains the build options and targets.

More Build Options

To build the library providing thread support you need to define either the environment variable 'THREAD=-lpthread' or the configure flag '---with-thread=-lpthread' (it is the default for the linuxeseg architecture). [Note: this is only tested on Linux for the time being.]

To build the library providing CERN RFIO (remote I/O) support you need to define either the environment variable 'RFIO=<path>/libshift.a' or the configure flag '---with-rfio=<path>/libshift.a'. For pre-built version of libshift.a see ftp://root.cern.ch/root/shift/.

To build the PAW and Geant3 conversion programs `h2root` and `g2root` you need to define either the environment variable 'CERNLIB=<cernlibpath>' or the configure flag '---with-cern-libdir=<cernlibpath>'.

To build the MySQL interface library you need to install MySQL first. Visit http://www.mysql.com/ for the latest versions.

To build the strong authentication module used by `rootd`, you first have to install the SRP (Secure Remote Password) system. Visit http://jafar.stanford.edu/srp/index.html.

To use the library you have to define either the environment variable 'SRP=<srpdir>' or the configure flag '---with-srp=<srpdir>'.

To build the event generator interfaces for Pythia and Pythia6, you first have to get the pythia libraries available from ftp: ftp://root.cern.ch/root/pythia/. To use the libraries you have to define either 'PYTHIA=<pythiadir>' or the configure flag '---with-pythia=<pythiadir>'. The same applies for Pythia6.

Installing the Source from CVS

This paragraph describes how to checkout and build ROOT from CVS for Unix systems. For description of a checkout for other platforms, please see ROOT installation web page (http://root.cern.ch/root/CVS.html).

(Note: The syntax is for `bash`, if you use a t(`csh`) then you have to substitute export with setenv.)
% export CVSROOT=:pserver:cvs@root.cern.ch:/user/cvs
% cvs login
% (Logging in to cvs@root.cern.ch)
% CVS password: cvs
% cvs -z3 checkout root
U root/...
U ...
% cd root
% ./configure --help
% ./configure <platform>
% gmake

If you are a part of a collaboration, you may need to use setup procedures specific to the particular development environment prior to running gmake.

You only need to run cvs login once. It will remember anonymous password in your $HOME/.cvspass file. For more install instructions and options, see the file README/INSTALL.

**CVS for Windows**

Although there exists a native version of CVS for Windows, we only support the build process under the Cygwin environment. You must have CVS version 1.10 or newer.

The checkout and build procedure is similar to that for Unix. For detailed install instructions, see the file README/INSTALL.

**Converting a tar ball to a working CVS sandbox**

You may want to consider downloading the source as a tar ball and converting it to CVS because it is faster to download the tar ball than checking out the entire source with CVS. Our source tar ball contains CVS information. If your tar ball is dated June 1, 2000 or later, it is already set up to talk to our public server (root.cern.ch). You just need to download and unpack the tar ball and then run following commands:

% cd root
% cvs -z3 update -d -P
% ./configure <platform>

**Staying up-to-date**

To keep your local ROOT source up-to-date with the CVS repository you should regularly run the command:

% cvs -z3 update -d -P

---

**Setting the Environment Variables**

Before you can run ROOT you need to set the environment variable ROOTSYS and change your path to include root/bin and library path variables to include root/lib. Please note: The syntax is for b(sh), if you are running t(csh) you will have to use setenv and set instead of export.

1. Define the variable $ROOTSYS to the directory where you unpacked the ROOT:

% export ROOTSYS=/root
2. Add ROOTSYS/bin to your PATH:

% export PATH=$PATH:$ROOTSYS/bin
3. Set the Library Path

On HP-UX, before executing the interactive module, you must set the library path:

% export SHLIB_PATH=$SHLIB_PATH:$ROOTSYS/lib

On AIX, before executing the interactive module, you must set the library path:

% [ -z "$LIBPATH" ] && export LIBPATH=/lib:/usr/lib
% export LIBPATH=$LIBPATH:$ROOTSYS/lib

On Linux, Solaris, Alpha OSF and SGI, before executing the interactive module, you must set the library path:

% export LD_LIBRARY_PATH=$LD_LIBRARY_PATH:$ROOTSYS/lib

On Solaris, in case your LD_LIBRARY_PATH is empty, you should set it like this:

% export
% export LD_LIBRARY_PATH=$LD_LIBRARY_PATH:$ROOTSYS/lib:/usr/dt/lib

**RootSys** is an environment variable pointing to the ROOT directory. For example, if you use the HPUX-10 AFS version you should set:

% export ROOTSYS=/afs/cern.ch/na49/library.4/ROOT/v2.23/hp700_uX102/root

To run the program just type: root

---

**Documentation to Download**

**PostScript Documentation**

The following PostScript files have been generated by automatically scanning the ROOT HTML files. This documentation includes page numbers, table of contents and an index.

- The latest revision of the Users Guide (5MB, 350 pages):
- ROOT Overview: Overview of the ROOT system (365 KB, 81 pages)
  ftp://root.cern.ch/root/ROOTMain.ps.gz
- ROOT Tutorials: The ROOT tutorials with graphics examples (320 KB, 81 pages) ftp://root.cern.ch/root/ROOTTutorials.ps.gz
- ROOT Classes: Description of all the ROOT classes (1.47 MB, 661 pages) ftp://root.cern.ch/root/ROOTClasses.ps.gz
**HTML Documentation**

In case you only have access to a low-speed connection to CERN, you can get a copy of the complete ROOT html tree (24 MB):
